Classes for the care and education of the unfortunate consumptive are being established and maintained; certainly a very wise precautionary measure against the dissemination of the disease, and at the same time guarding against ignorance with its inevitable consequences. Do we not in the same measure owe a duty toward the community in the case of the child that shows a tendency to suffer or already suffers from an infectious mental ailment with a proclivity to exert a baneful influence upon the plastic mind of its playmates and schoolmates in its youth with the dire consequences to the social body in their adult life? The segregation of the exceptional child is just as much indicated, as in the case of the consumptive. Ungraded and special schools and classes, such as are now being connected with public school systems, can do very good work with the so-called pseudo-atypical children—that is to say, those with whom a more individualized instructional training or discipline will suffice. Pseudo-atypical children are such whose progress in school had been hindered by repeated illness, change of schools, slower rate of development, or physical difficulties, such as lameness and deformities, slightly impaired vision or hearing, etc. Also children of unusually rapid physical development, without the genuine pathological precocity, and that class which is difficult of management (the naughty, troublesome, spoiled children) can be very satisfactorily reached by individual attention in such classes. But the atypical child requires, in most instances, irrespective of whether rich or poor, a removal from its home, which often has been a direct or indirect cause of the atypical conditions, into an environment where all educational forces can be scientifically coordinated. They require the closest observation and study, so that each manifestation can be understood in its causal-

ity and as a developmental symptom. Educators and physicians must cooperate in the study of the problem of the atypical child. It certainly is an appalling mistake to mass these exceptional children together with the normal ones in classes, the curriculum of which requires some kind of common proficiency in a large number of studies, the maintenance of which depends upon lockstep methods of teaching and of such reaction by the child as must inevitably destroy in the exceptional child the ability of asserting its individual growth. In fact, what is best and strongest and necessarily individual is as a rule irreparably curtailed and deformed by this mechanical grading, which is worse even in the well-equipped city schools than in those of rural districts, where one finds more freedom for the pupil if the teacher is at all conscious of the possibilities of the exceptional child.

Among some exemplary institutions Dr. Groszman's school for atypical children is the best evidence of how the apparently impossible can become an actual possibility in the matter of turning the abnormal child into a useful member of society. We have attained to the age of analysis and synthesis and have wrought marvels in the field of scientific research through the application of these principles. Dr. Groszman's school has proven eminently successful by applying these principles to the education of the exceptional child by analyzing its potentialities and synthesizing its units in proper proportions, thus creating a new equilibrium, a new readjustment in a new environment, a rearrangement of erratic ideas into normal streams of thought, and thereby inculcating new habits leading to normal, useful action. I plead that humanity, as well as selfishness; that charity, as well as justice, imperatively demand the education of the exceptional child in a manner suitable to its needs at public expense.

FURTHER OBSERVATIONS ON ALCOHOLIC GASTRITIS AND ITS RELATION TO EXPERIMENTAL GASTRITIS IN ANIMALS.*

By NELLIS B. FOSTER,

NEW YORK.

In a preliminary report[1] in 1904 I called attention to the effects on gastric secretion and motility of habitual excessive use of alcoholic beverages. That alcohol produces a disturbance in normal digestive processes has, of course, been long recognized by clinicians, but no one up to 1904 appeared to have studied in a systematic way the state of the secretion found in the stomach of chronic alcoholics.[2] This question is of peculiar interest because in the protracted use of alcohol we have in fact a long continued experiment which shows in some measure the effect which an irritating substance produces upon the gastric mucous membrane in man.

Those who habitually use alcohol in excessive amounts are subject to a certain train of symptoms with which clinicians are familiar; the most prominent of these being the morning retching. This nausea disappears after taking some alcoholic drink or after breakfast. If one investigate the secretory function of the gastric glands in these individuals it is found that the secretion is below normal in amount; the rule is that there is no free hydrochloric acid present, or if there be any it is only a trace. There is also an excessive amount of mucus. This diminution in the amount of secretion, along with the presence of an abnormally large amount of mucus, is to be understood as indicative of a gastritis, reflecting in this case, I think, a twofold effect, depression of the acidophylic cells and irritation of the mucous cells. It was constantly noted in my earlier cases that if a full hour be allowed to elapse before removing the test meal the amount recovered was very small, often not enough for an analysis, although lavage showed the stomach to have been emptied. It became necessary then to supplement the routine test breakfast by a larger meal which would remain longer in the stomach and give better data in respect to the motility. The modified Riegel meal best answered these demands and also served as a control on the data secured from test breakfasts. The results of more careful study confirmed the statements made in my first paper, namely, that there is an increase in motility causing the food to leave the stomach sooner than the same food substances do in normal persons.

Before discussing the causes of this condition I wish to mention that disturbances in the normal gastric secretion are not confined to those alcoholic patients who present the characteristic symptoms of the disorder. Not a few who give a history of over-indulgence in alcohol have no symptoms referable to digestion; yet when the gastric functions are investigated they are not found to be normal. There is seldom an anacidity as in the first group, but the secretion is very much diminished, the free hydrochloric acid not exceeding 10. This would suggest that we have to do in this group of cases with a less well developed grade of the same disorder, a supposition borne out not only by the absence of symptoms, but by the less profuse secretion of mucus; moreover, there is no evidence of hypermotility at this stage of the disease.

Aside from neurogenic causes, we can conceive of the stomach emptying itself more quickly in consequence of readjustment of the normal factors to meet abnormal demands. Normally the pylorus relaxes for the passage of chyme when free acid comes in contact with the antrum, but here there is no free acid, and either there must be a readjustment or serious results would ensue. It is conceivable also that the muscular tone of the pyloric sphincter is, under these circumstances, considerably impaired. That there is a hyperkinesis in this form of gastritis is then exactly what might be expected on purely theoretical grounds. Then, too, there is always a marked power of compensation in organic functions of which the increased motility may be regarded as an example, since, with the amounts of secretion found peptic digestion cannot well proceed at its optimum, and the passage of the food to the duodenum would initiate the tryptic process which is normally more efficient in proteolysis and digestion would continue uninterrupted. Briefly, this gastric disorder may be classified into two groups, first, the less advanced pathological state, where there is serious impairment in the activity of the gastric glands, but free, unbound acid still is present in the test meal and the food remains in the stomach for a normal period. Second, the advanced type of gastritis with anacidity, copious mucous secretion and hyperkinesis.

To the stomach not inured to alcohol this substance acts as a stimulant to gastric secretion, a fact

*Read before the American Gastro-Enterological Association at St. Louis, Mo., June 6 and 7, 1910.

first demonstrated by Sawriew in Pawlow's laboratory. In exciting secretion alcohol stands in contrast to other irritating chemicals which have been studied in this relation; silver nitrate, for example, inhibits acid secretion, but causes a copious secretion of mucus. On this account it seemed of some interest to note what effect repeated doses of alcohol would produce in dogs having the Pawlow double stomach. I imagined that while alcohol might cause an increase of secretion at the beginning of its use, this effect being in the nature of an excessive stimulation, it would, in a short time, be followed by a diminished secretion representing either a fatigue inhibition or a change in the gland substance. This in result is what occurs. If alcohol be mixed with the food of these dogs there is an increase in the amount of gastric juice beyond what is found in control dogs with the same diet. But if the alcohol be given several days in succession there is a prompt falling off after a few days in the amount of juice secreted. At the same time there is a gradual increase in the mucous secretion from the small stomach. The conclusion at which one would arrive from this experiment is that the initial stimulation of the gastric glands caused by alcohol is followed by a period of diminished irritability to this stimulus, and such an idea is quite in accord with general physiological principles. This is in unison also with what is known of the action of alcohol in other relations; a transitory stimulation while the organism is unaccustomed to its presence. The increasing mucous secretion indicates an increasing grade of irritation of the mucosa, in which respect alcohol is somewhat analogous to silver nitrate Pawlow's interpretation of this mucous secretion is that it is protective in its action, and is increased whenever substances irritating or injurious to the glands come in contact with the gastric mucosa.

With regard to increased gastric motility in experimental animals I have never had an opportunity of noting it following the ingestion of alcohol, probably because I have not endeavored to secure the maximum results by long continued use. It has happened several times, however, that dogs have developed what appeared to be a chronic gastritis due to faulty feeding; an abnormally small amount of secretion with only a trace of free acid and enormous amounts of mucus, and in such dogs I have repeatedly observed that the stomach emptied itself in about three-quarters of the normal time.

PRIMARY STREPTOCOCCUS DIPHTHERIA.*

By DAVID H. ORGEL, M.D.,

NEW YORK.

ADJUNCT ATTENDING SURGEON HAR MORIAH HOSPITAL.

While it is frequent to find pseudomembrane upon the tonsils, pharynx, larynx, and in the trachea, secondary to scarlet fever and measles, due to the streptococcus, I am going to confine myself to the primary infection of the tonsils, pharynx, etc., accompanied by the formation of a pseudomembrane with complications produced by streptococcii.

In an examination of the literature on this subject, we find that most authorities, Holt[1], Pfaundler and Schlossmann,[2] Osler,[3] Tyson,[4] Northrup,[5] and Park[6] refer to primary streptococcus diphtheria, usually as a mild affection with no complications and sequelæ, in which the pseudomembrane is usually limited to the tonsil. Park,[7] in the study of eleven cases, notes, however, instances where the pseudomembrane extended into the pharynx, larynx, and nostrils, and among these, two cases with albumin in the urine. Kerley,[8] notes a case where the patch extended further than the tonsils and was complicated by enlargement of the cervical glands. This has also been substantiated by Fischer[9] and Koplik[10] admits that suppuration of these may occur.

Prudden,[11] in an exhaustive study of 24 cases of diphtheria due to the streptococcus, reported that nine were simple (primary), uncomplicated by any previous disease, the membrane extending over the tonsils, pharynx, larynx, and bronchii—in one case albuminuria and in another parenchymatous degeneration of the kidneys.

I believe that we have never accorded to this disease the frequency of the severe type in which it occurs, and it will be my purpose to report to you some of the cases which I have seen, with their complications and sequelæ. It is a well-known fact, as proven by Baginsky, Park, Morse, and others, in an examination of the cultures of the throats of patients that 25 to 35 per cent. of cases diagnosed as true diphtheria are cases of infection with the streptococcus or streptococcus and staphlococcus.

With a record of 100 of these cases in private practice, I have found that 80 per cent. have been of the mild or moderately severe type, with no complication, except in some cases slight glandular swelling and albuminuria. In the other 20 per cent. the disease was severe in character with complications of severe glandular enlargement with suppuration and acute exudative nephritis. In the diagnosis of all of these cases no reliance was placed on the clinical manifestation of the disease, but upon the result of the microscopical examination of cultures made from the membrane on the first, second, and third day of the disease, showing the absence of Klebs-Loeffler, pseudodiphtheria bacillii, or pneumococcii, but the presence of streptococcii in pure culture or their predominance over straphlococcii.

As was said by Jacobi[12] "The tonsils being a portal of microbic and toxic invasion, any exudate which extends from the tonsils to its neighborhood, brings with it, immediate swelling of the lymph glands," I have found this uniformly in the severe cases, to wit: Swelling of the cervical lymph glands.

The kidneys in these twenty cases have all been involved, with the diminution and sometimes the entire suppression of urine. Upon examination albumin was present, microscopically epithelical cells, red blood cells, and sometimes casts.

The mortality in these twenty severe cases has been 9 or 45 per cent. Park says the mortality may be 0 to 20 per cent.

The onset in most of these cases was usually sudden with chills, vomiting, and high temperature—104-5 degrees F. The patients were restless, apathetic and sometimes delirious. The throat showed an erythema of the tonsils and pharynx, and within 12 to 24 hours the tonsils and pharynx were covered with a dirty yellowish membrane, which was at first easy to remove. The membranes extended to the Posterior nares in three cases. The cervical glands were immensely swollen and tender at this time. The symptoms never abated as in the

*Read before Har Moriah Clinical Society, April 10, 1910.

mild cases, on the third or fourth days, but remained the same. When the membrane was forcibly removed it left a raw area which bled freely. The urine at this stage showed its changes, being very much diminished, and in the fatal cases nearly suppressed.

The severity of the symptoms in those cases that recovered abated from the tenth to the fourteenth day, and went on to resolution, which was slow. The membrane first disappeared; then the glandular swelling, and lastly the kidneys cleared up, or the inflammation became subacute and later chronic.

In the eleven cases that recovered, there was suppuration of the glands, requiring incision in five. The examination of the urine of those cases within the last two weeks show that four are suffering from a chronic affection of the kidneys. Of the other nine, three died of uremia, and six from toxemia of the disease.

As an instance of the severity of these cases, let me cite you the history of three as examples.

Case I.—B. F., 11 years old, called January 26, 1910. Previous personal history: The child had two attacks of bronchopneumonia, and occasional attacks of follicular tonsillitis and measles. Present history: On January 25 she suddenly became ill with chill, vomiting, headache, and fever; vomiting was continuous; she was restless and at times delirious. Examination: The face was flushed, the child restless and vomiting. The temperature was 104½° F., respiration 28, pulse 120. The lungs, heart, and abdomen were negative. There was no enlarged spleen. There was erythema of the tonsils, slight membrane on posterior pharynx. A culture was taken. The urine was scanty and dark red in color; albumin was present, and microscopically epithelial cells, and red blood cells. On January 27 the condition of the patient was worse. The child was restless and delirious. The temperature was 105° F. There was a pseudomembrane covering tonsils and extending. The cervical glands were swollen. 5,000 units diphtheria antitoxin were given and a culture taken. Ten c.c. of urine was passed in 24 hours. January 28: The pseudomembrane extended over the tonsils, pharynx, and posterior nares. The glands were immensely swollen; 5,000 units diphtheria antitoxin were given and a culture taken. This condition continued until February 6 when the temperature began to drop gradually and the pseudomembrane started to disappear, leaving necrotic areas. The urine increased in amount. On February 10 the glands were diminishing in size. The urine still contained albumin and epithelium, but was clearing up. The report on the cultures showed no Klebe Loeffler bacilli, no pseudodiphtheria bacilli to be present, but a great many streptococci and many staphylococci.

Case II.—Child S., 10 years old. called March 17, 1903. Present personal history: Child had two attacks of diphtheria, enlarged tonsils, bronchitis, and pneumonia, but otherwise had been well. Present history: On March 16, at night, the child vomited and complained of pain in the neck, and headache. The temperature was 105° F., the pulse 130, and the respiration 28. The lungs, heart, and abdomen were normal. The throat was red, swollen, and with patches of membrane on tonsils and pharynx. The urine was not examined; 3,000 antitoxin units were given and a culture taken. On March 18 the culture was negative, containing streptococci. The cervical glands were swollen and tender; the patch covered the tonsils, pharynx, and the nose was discharging; the temperature was 105° F. 3,000 units diphtheria antitoxin were given and repeated in the evening. The urine contained albumin, red blood cells, and epithelium.

This condition continued without improvement until April 1, when she started to improve. The throat cleared up, the urine cleared up, but the glands on both sides of neck underwent suppuration, and were incised. For more than four weeks the child was confined to bed.

Case III.—M. S., 2½ years old. Called January 11, 1910. Previous personal history: The child had always been well, except for occasional attacks of bronchitis and tonsillitis. The child became ill on January 10, complaining of headache, pain in the throat, and high temperature. There was no rash upon the body. The child was prostrated, face flushed, temperature 103° F., respiration 30, and pulse 140. The lungs, heart, and abdomen were negative. There was redness of the tonsils and pharynx, the glands were swollen, and there was a small patch on the pharynx. 5,000 units of diphtheria antitoxin were given and culture taken. The urine was dark brown in color, containing albumin, red blood cells, and epithelial cells. January 12: The culture showed no Klebe Loeffler bacilli, no pseudodiphtheria bacilli, but streptococci; 10 c.c. of antistreptococcus serum was given and repeated in the evening. The child appeared to be worse than yesterday. The temperature was 104° F. The urine was small in amount—not over one-half glass (water tumbler) in 24 hours. Another culture was taken. January 13: The child was still no better, was delirious continuously; the glands of the neck were immensely swollen; the throat was the same; the urine not more than in last 24 hours. 5,000 units diphtheria antitoxin were given. Culture, same report. January 14: The child was in the same condition. The urine was suppressed for 12 hours, then after a hot rectal irrigation 2 ounces were passed. This continued until January 19, when child died in uremic coma.

In the treatment, I have found very little of any avail, except thorough toilet of the mouth and nose, with stimulation to tide the patient over the time until the toxemia subsides. Diphtheretic serum has been given even in large doses, up to 20,000 units without any effect. Antistreptoccus serum has also been given without effect. The only thing I have found of value is the spraying of the throat with peroxide of hydrogen, ice bag to the neck, and douching of the mouth and nose with salt solution. When the urine becomes scanty or suppressed, hot rectal irrigations or hot water bags to the region of the kidneys are advised. I have not seen them able to withstand the hot packs or the hot bath without great prostration. If the cervical glands show evidence of pus, I have incised freely.

Summarizing these results, we find:

1. That the severe form of primary streptococcus diphtheria occurs oftener than we have been led to believe.

2. That complications of suppuration of the cervical glands occur frequently.

3. That complications of acute exudative nephritis occurs in all severe cases and in some becomes chronic.

In conclusion, let me thank Dr. N. Kruskal for his cooperation in this report and for microscopical examination of the cultures of these cases.

277 RIVINGTON STREET.

AEROTHERAPY.

BY J. GEORGE SAUER, M.D.,

NEW YORK.

FELLOW NEW YORK ACADEMY OF MEDICINE.

THE knowledge that practically every city resident has had or will have and may recover again and again from tuberculosis, together with a knowledge of the physical fortification against its invasions, might produce in the laity a phthisiophobia which could serve as a prophylactic measure of the wholesome educational variety and thus enable them to avoid many of the debilitating infections, not only of tuberculosis, but of many of its catarrhal forerunners.

That the normal individual is quite competent to resist, and does continually resist, its invasion is evident from the existence of this disease germ on the nasal mucous membrane of every subway passenger, pedestrian, and city resident, practically all the time, and the postmortem discovery of the healed pulmonary lesions by the pathologists and their more frequent antemortem discovery by the radiologist are conclusive evidences of the universality of this disease which was formerly regarded as inevitably fatal.

That the treatment of the person sick with this chronic disease has justly passed out of the hands of the city physician, and is now a matter of prophylaxis and the fortification of the natural human forces of physical resistance is manifested by the establishment and maintenance of the many municipal and private institutions in the location where aerotherapy is practically the only remedial measure. The city resident is now living in an age when he is compelled to exist, at least for a large percentage of the time, in an atmosphere which has just left the lungs of other individuals. This unfortunately is a necessary evil of existence in the larger cities, but the rebreathing of the exhausted atmosphere of one's own bedroom is, even for the city resident, an unnecessary and wanton endangerment, and its continuance is rather an exhibition of ignorance; for, if we cannot improve the aerial environment of the city resident during his waking hours, we can with ease and absolute certainty do so during the long hours of his sleep, which represent at least one-third of the whole time of his existence. It was with this idea in mind that the writer some time ago devised the bed herewith illustrated, and he has used this form of open-air sleeping continuously and satisfactorily for the past five years.

It consists of an ordinary single iron bedstead from which the front legs have been moved to the center of the frame; this permitting the entire legless portion to be pushed up to and out of the window, and then the window to be closed across the sleeper's waist line. This leaves the head and chest in the open air, but maintains the room temperature for the lower portion of the sleeper.

The sensation of sleeping with the upper half of the body out of one's back room window (if necessary under an awning) is not only healthful, but delightful. The resulting restful, quiet sleep out in the open air causes one to wake up invigorated, rejuvenated, and with a pleasantly large appetite for breakfast. With the head well hooded and the body warmly clad, the coldest night in winter is no bar to its healthful enjoyment. All the writer's family, as well as many of his patients, to-day prefer to sleep with their heads out of the window, and without a single exception they all fail to enjoy sleeping indoors; in fact, many of them wake up continuously for air while thus confined, and this in my opinion is evidence conclusive of its universal adoption when once its enjoyment becomes universally known.

This illustration shows the head of the cot projecting from the window, the sash of which can be lowered; the awning can be let down if desired.

In the heat of the summer evening is to be found its greatest delight and comfort, for from whatever point of the compass the breeze chooses to come, the sleeper is bound to receive its beneficent influences. Rain, snow, or neighbors only necessitate the awning, which can be lowered or partly lowered with one hand and without making it necessary for the sleeper even to raise himself in the bed.

New York, August 13, 1910.

RESECTION OF THE POSTERIOR SPINAL NERVE ROOTS.

In a recent issue of the MEDICAL RECORD there was a brief editorial reference to this mode of treatment of spastic paralysis, but with this subject we are not directly concerned in the present discussion. When Förster published in 1909 his first report of work done since 1907, there was, if we remember rightly, no reference to earlier operators; and the Breslau neurologist is undoubtedly entitled to whatever credit is due for first using this resection for spastic paralysis. Clark and Taylor of New York were not far behind in the claim of priority; and the operation was soon pressed into service for the relief of the gastric crises of tabes dorsalis. A singular feature in the reports published up to and including Förster's first article is absence of reference to much earlier cases of nerve-root resection as a general procedure, without reference to the aim of the operation. Förster, as well as others who have used the method, was plainly at considerable pains in looking up a possible literature of the subject. Laminectomy, without reference to resection of nerve-roots, has, of course, its own literature.

In an article on posterior root resection for tabic crises in the *Münchener medizinische Wochenschrift* for July 5 Flörcken has been at pains to trace the old and forgotten literature of this operation. The latter was done at least as far back as 1888 for neuralgia, and Dr. Abbe of New York is mentioned as one of the earliest operators. Chipault, so well known for his tireless work on the literature of surgery of the nervous system, published in 1895 a small series of known cases of this character. The half-dozen or so of cases then known shows that the intervention was formidable, and that the operative mortality was high; but that the success in recovered cases was perfect. During the next two years Chipault kept the subject alive by reporting a few more cases. But the question then slept for a decade until Förster, as a result of exhaustive investigations extending over several years, ventured to demonstrate that "radiculectomy" might be made a safe and satisfactory procedure in spastic paralysis.

There is one break in this interval of silence, in which—as often happens—peculiar traumatisms entailed some emergency procedure. An American surgeon, in 1904, performed root resections in connection with the treatment of extensive injuries. The fact that no benefit attended these operations naturally served to keep them in the background.

The silence in literature as to radiculectomy—which silence had become confirmed when Förster devised his method—seems to have been due to the high percentage of fatalities and to negative results. The few brilliant cures of neuralgia effected between 1888 and 1898 seem to have been more than neutralized by unfavorable results. It is therefore small wonder that Förster, in reviewing the operation, believed himself a pioneer from every point of view.

VOTES FOR WOMEN AND THE BIRTH RATE.

As the agitation of the suffragists and suffragettes for an equal voice with men in legislation goes on, the search for arguments pro and con is bringing all sorts of questions to the fore and presenting them with all their bearings on the main subject. One argument of those who would oppose the movement is concerned with what is commonly called race suicide. The movement is characterized by them as a direct menace to the race and to public health. The deterioration of inhabitants of towns is held to be greatly due to the fact that mothers, instead of staying at home to nurse their families, are generally away from home, either on pleasure bent or in order to earn money. Therefore, the contention is made that to encourage women in their endeavors to become voters would be to add further impetus to the already too prevalent neglect of home duties evinced by modern women.

There is no doubt that in this country and in Great Britain the present day woman shows a decided distaste for or disability to assume home duties. In Great Britain mothers of the poorer class work in factories, leaving their children to the care of strangers, and in this country similar conditions exist, although probably not in so accentuated a form. The point then is, does it seem likely that the granting of votes to women will render them still more neglectful of their children and home, having a bad influence on the birth rate and on the future of the race?

Opponents of the movement assert that nine-tenths of the decline of the birth rate is preventable. It is greatest in towns employing woman labor. Woman labor involves a decline of the birth rate. Consequently, would not giving woman suffrage promote female independence, female labor, and decline of the birth rate? On the other hand, the advocates of votes for women declare that there is no reason to presume that female suffrage would affect injuriously the birth rate. In support of this view, they point to New Zealand and to Australia, those countries in which reforms of all kinds are ever being initiated. In New Zealand, up to the time of the granting of woman suffrage, the birth rate was greatly on the down grade. Since the movement became law, some seventeen

years ago, the birth rate has increased because, it is said, motherhood has become intelligent and thoughtful. It is claimed that the same result has occurred in Victoria, where woman suffrage has also come to pass, and that in New Zealand and Australia, now that women have a voice in furthering legislation for the benefit of their children, they desire children and make every effort to reduce infant mortality by feeding naturally and by other means of rearing children in a healthy manner. It is hardly fair, however, to compare the conditions in a purely agricultural country like New Zealand, or even in Australia, with those which exist in the cities of Great Britain and of America, besides which the movement in the lands under the Southern Cross has not been long enough established to warrant any definite conclusions as to its results.

More About Cancer.

The report of the British Cancer Research Fund has been issued recently. Dr. Bashford and his coadjutors give a conservative and cautious account of the results obtained from their researches and investigations into the cause of the disease. No striking progress, they say, has been made in solving the mystery of the origin of cancer, nor does the report lead us to hope that the end is yet in view. With the origin of the disease not known, it would be rash to predicate a successful mode of treatment. This appears to be the opinion of a large proportion of the medical profession, in fact the majority of surgeons have little hesitation in stating their views that at present the only reliable means of treating cancer is by the knife. Dr. Gilbert Barling at the meeting of the British Medical Association, the special report of which appears elsewhere in this issue, voiced the opinion of most surgeons when he said that operative measures were, as yet, the sole effective methods of relieving and curing the most deadly forms of cancer. Of course, it is well known that the knife is frequently futile in such cases, but it is said to afford the one reasonable chance of saving life. Early diagnosis and prompt operation, therefore, offer the best opportunities of cure. Much has been claimed for radium in the treatment of cancer and Dr. Louis Wickham of Paris, who also read a paper on the subject at this meeting of the association, is, with Abbe of this city, one of the best known exponents of this form of treatment. However, the form of cancer thus successfully treated by radium is generally localized, superficial, non-inflammatory, and of comparatively small size. It is true that claims have been made by several well known specialists that deep-seated malignant tumors have been cured by the agency of radium, but experience has been too limited for even the most enthusiastic to assert that radium is a cure for such growths. There is no doubt that the rays emanating from radium exercise a selective action on certain diseased tissues, and in many cases cause their destruction. Therefore the rôle of radium would seem to be its employment in cases of superficial cancer of the kind noted above. Dr. Wickham has warned medical men that in all other cases than those of cancer of the skin it is their duty before applying radium to decide if other agents will not give better results. This is probably sound advice, in spite of the many wonderful cures by radium which Abbe has reported from time to time during the past four years. It must be borne in mind, however, that frequently radium may be a valuable auxiliary of the knife. Indeed, in the opinion of the best authorities, the parts played in the treatment of cancer by operative means and radium are different, but they may be, on occasions, employed together with good effect.

Malta Fever.

In a lecture delivered at the Polyclinic, London, on May 2, and published in the *Medical Press and Circular*, July 13, F. M. Sandwith discussed Malta fever. In the first instance, it was explained that Malta fever was the term given to the disease because Bruce discovered the causal microbe in Malta and it was there where the Royal Commission discovered the interesting fact that this fever is communicated by milk, generally by goats' milk, although cows, if infected, can also communicate it. In 1886 Bruce discovered the specific microbe, a diplococcus, the *Micrococcus melitensis*. The gardens in Malta are few, there is little grass, and there are hardly any cows. The people use goats' milk, and the goat is an unclean feeder, living on any garbage it can find. The goatherds bring the animals to the door, the housekeeper produces the jug, and the man, with unwashed hands, of course, milks the goat. When the British Royal Society, combining with the War Office and the Admiralty, sent out a commission to Malta to study the question nobody blamed the goat or the milk supply. It was, however, accidentally found that the goats' blood gave the same agglutination reaction as did that of a human being suffering from the same disease. It was then discovered, on further investigation, that at least 50 per cent. of the goats in Malta were suffering from the disease and that at least 10 per cent. of the goats which were being brought round to the houses to supply the milk were giving the disease at the same time. The commission succeeded in persuading the military and naval authorities to banish goats' milk from hospitals, barracks, and certain private houses. In all places in which goats' milk is not used there is no Malta fever. A section of the British medical profession, that section which disbelieves in vivisection, says that the fever in Malta had suddenly come to an end and that the result was not due to any precautions taken. But the civilian population of Malta, which is not under control of the War Office or the Admiralty, still drink goats' milk and still suffer from Malta fever. This disproves the statements of the antivivisectionists and likewise supplies remarkably strong negative proof that Malta fever is spread by infected goats' milk. The treatment of the disease consists in being certain of the milk supply, otherwise a patient is treated in the same way as one with typhoid fever would be treated, only with not so rigid dietetic regulations as are prescribed for the latter malady. The drug treatment is symptomatic and the sole drug found to be of any real use is bichloride of mercury, given with the view of cleansing the intestines.

Transplantation of the Kidney.

Owing to the frequency and seriousness of the diseases of the kidney, much work in the surgery of these organs has been done, and among other operations experimental transplantation of them has been attempted in animals. The conclusions

given by E. Villard and L. Tavernier in an article in *La Presse Médicale*, for June 29, 1910, are these: Autotransplantation has given durable results; homotransplantation permits the survival of the kidney, and to all appearance a normal function, but there is as yet no proof that these results will remain durable; heterotransplantation is not as yet proven to be possible. There are still great opportunities for experimentation in this line of work. In order to give the best results so far obtained the interruption of the circulation must be as short as possible, not more than half an hour to an hour; longer interruption causes necrosis of the kidney. Perfusion is both useless and injurious to the operative results. The ureter should be made to open into the bladder and not externally. In the choice of the arteries with which anastomosis is to be made the femorals and iliacs should be eliminated; the renal and the aorta are physiologically the best, but the technique necessary renders their choice impossible. The splenic by its accessibility, its calibre, and its functional conditions appears to have the greatest number of advantages.

News of the Week.

Vital Statistics of New York.—During the month of June the total number of births in the State of New York was 16,782, and of deaths 10,893, while for New York City alone the figures were 10,400 births and 5,946 deaths. During the month there were 6,837 cases of measles with 136 deaths; 2,692 cases of tuberculosis with 1,055 deaths. The suicides numbered 142, and 124 persons lost their lives by accidental drowning. The deaths from old age were 146, while 520 occurred in early infancy. It is interesting to note that while the excess of births over deaths was 4,454 in New York City, the excess in all the rest of the State was only 1,435.

Dr. Isham G. Harris of Poughkeepsie, New York, has been appointed by the State Commission in Lunacy as superintendent of the new Mohansic State Hospital, at Lake Mohansic, near Peekskill. Dr. Harris was graduated from the New York University Medical School in 1890. The appointment was made from the Civil Service eligible list.

Plague in China.—An epidemic of plague in Canton, China, is reported. A hot and dry summer is said to have made health conditions in the city unusually bad.

Dr. Benjamin F. Beardsley of Hartford has been nominated on the Prohibition ticket for Lieutenant-Governor of the State of Connecticut.

Iowa State Boards.—The Iowa State Board of Medical Examiners recently elected Dr. George E. Decker of Davenport as its president. The State Board of Health elected as president Dr. A. C. Moerke of Burlington. Dr. G. H. Sumner of Waterloo was reelected secretary; and Dr. Henry Albert of Iowa City was appointed director of the State laboratories, and Prof. Charles M. Kinney of Des Moines, State chemist.

Osteopaths Continue Fight.—Another move was made in the long fight which the osteopaths are carrying on for recognition by the Board of Health of New York, when a motion was argued before Justice Putnam of the Supreme Court of Brooklyn for an injunction to restrain the Board of Health from enforcing Section 163A of the Sanitary Code. This section provides that no transit permit shall be granted for the burial of the body of a person who has been treated by an osteopath until the body has been examined by a regular physician. Decision was reserved.

Gift to Dr. Grenfell.—The forty-foot hospital tender "Yale," which was built expressly for the work of Dr. Grenfell on the Labrador coast, and was presented to him as a wedding present, is reported to have arrived safely at Indian Harbor, Newfoundland. The "Yale" is ketch rigged, with an auxiliary engine using kerosene, as gasoline cannot be obtained in Labrador.

New Zoological Laboratory.—Plans have been completed for the University of Pennsylvania for what is expected to be the finest zoological laboratory in the world. The building will be three stories high and of fireproof construction, and will occupy a lot 216 by 256 feet. The cost will be about $300,000. Work on the new building will be begun in the autumn.

Dr. F. M. Shook, Medical Corps, U. S. Navy, has been detailed to conduct lectures and laboratory courses in tropical medicine at the New York Post-Graduate Medical School during the months of August and September.

Dole for the Blind.—The Department of Charities of New York made the city's annual distribution of money to the needy blind last week, when more than seven hundred persons living in the Boroughs of Manhattan and the Bronx received $48 each. The entire appropriation for the city is $70,000. The majority of the applicants were newsdealers, but chairmakers and basket-weavers and a few pianists were included.

Esperanto Congress.—The Sixth International Esperanto Congress will be held in Washington on August 14 to 18. Delegates representing twenty-two nationalities are expected. The entertainment provided will include a production of "As You Like It" in Esperanto.

Instruction for Health Officers.—The twelfth annual School of Instruction for Health Officers was in session at the hall of the Kellogg-Hubbard Library, Montpelier, Vermont, from August 1 to 4, inclusive. The program included papers by Dr. George M. Kober of Georgetown University, Washington; Dr. Livingston Farrand, secretary of the National Association for the Study and Prevention of Tuberculosis; Dr. S. Dana Hubbard of Brooklyn, N. Y., and Dr. A. D. Melvin of the Bureau of Animal Industry, Washington.

Railway Accidents.—During the first quarter of the present year 1,100 persons were killed and 21,232 were injured on the steam railways of the United States. These figures show an increase of 466 killed and 6,110 injured, as compared with the same period of last year. On the electric railways 19 were killed and 669 were injured.

Opium Conference Postponed.—In reply to the proposal of the United States that some date in September be agreed upon for the International Congress to devise measures for combating the opium evil, the Chinese Government has stated that its representatives cannot be ready for the conference before some time in November. It is planned to hold the sessions of the congress at The Hague.

Practical Courses in Abdominal Surgery.—It is announced that a free course in abdominal surgery will be given during October at Duesseldorf, Germany, by Professors Witzel and Opitz and Dr.

Janssen; those attending the course can also attend the courses in internal medicine, especially those having reference to gastroenteric diseases. The program can be obtained from the Secretary of the Duesseldorf Academy, No. 1 Mooren Street.

City Death Rate.—For the week ending July 30, the death rate in New York was 18.80 per 1,000 of population, an increase over the corresponding week of last year, when the rate was 16.96.

Cholera and Coal Famine in Russia.—The epidemic of cholera in Russia is especially severe in the coal-mining districts on the Donets River, in the southern part of the Empire, and a general exodus of miners has been the result. The Government has been appealed to for more strenuous measures in combating the scourge in this region, as the output of coal from the infected districts has already been reduced to one-half the usual quantity, and a coal famine is feared if the exodus of miners is not checked.

Civil Service Examination.—An examination under the Civil Service Commission will be held early in September for the purpose of filling the position of statistician and editor to the State Commission in Lunacy, Albany, N. Y., which will be open only to male residents of the State of New York. Candidates must have a college training and some knowledge of medicine or biologic science, and must have completed a course in statistical work. Further information may be obtained from the Civil Service Commission of Albany, N. Y.

The American Electro-Therapeutic Association.—The twentieth annual meeting of this association will be held at Saratoga Springs, N. Y., on September 13 to 15, 1910. Programs and circulars may be obtained from the secretary, Dr. J. W. Travell, 27 East Eleventh Street, New York, N. Y.

Obituary Notes.—Dr. Leander S. Porter of Port Clinton, Ohio, a graduate of the Cleveland University of Medicine and Surgery in 1880, died on July 26, aged 81 years.

Dr. Thomas Cammack of Milford, Ind., a graduate of the George Washington University, Medical Department, Washington, D. C., in 1845, died at his home on July 9, aged 88 years.

Dr. Jules F. Menestrina of St. Louis, Mo., a graduate of the Medical Department of the Washington University, St. Louis, in 1890, and a member of the American Medical Association and the State and St. Louis County Medical Societies, died at his home of paralysis on July 26, aged 43 years.

Dr. David F. Woods of Philadelphia, Pa., a graduate of the Medical Department of the University of Pennsylvania in 1864, a Fellow of the College of Physicians of Philadelphia, and a member of the American Medical Association and of the State and Philadelphia County Medical Societies, died at his home on July 28, aged 72 years.

Dr. Joseph W. Crowley of Philadelphia, Pa., a graduate of the Medical Department of the University of Pennsylvania in the class of 1895, died at his home of pneumonia on July 23, aged 43 years.

Dr. Benjamin F. Emrick of Carlisle, Pa., a graduate of the College of Physicians and Surgeons of Baltimore in the class of 1881, and a member of the State and Cumberland Medical Societies, died at his home on July 26.

Dr. William G. Perry of Exeter, N. H., who was graduated from the College of Physicians and Surgeons, New York, in 1847, died recently at his home, aged 87 years.

Obituary.

CHARLES JEWETT, M.D., Sc.D.

BROOKLYN, NEW YORK.

Dr. Charles Jewett, president of the Medical Society of the State of New York, died of apoplexy at his home in Brooklyn on August 6, aged 70 years. Dr. Jewett was a graduate of Bowdoin College and received his medical degree from the College of Physicians and Surgeons, New York, in 1871. He was a member of the Medical Society of the County of Kings, of which he was elected president in 1878, serving until 1880, of the Medical Society of the State of New York, and of the American Medical Association. He was also a member of the New York Academy of Medicine, the American Academy of Medicine, the Brooklyn Gynecological Society, of which he was president in 1893, the Brooklyn Pathological Society, and the New York Obstetrical Society, of which he was president in the year 1894, and also a member of the gynecological section of the Royal Society of Medicine of Great Britain. In 1880 he became professor of the diseases of children and obstetrics in the Long Island College Hospital, and in 1890 was appointed gynecologist to the same institution. He was also consulting obstetrician to the Kings County Hospital, consulting gynecologist to the Bushwick, the Swedish, and the German Hospitals, and consulting surgeon to St. Christopher's Hospital. He was the first surgeon in America to perform symphyseotomy.

The death of Dr. Jewett removes from the ranks of the profession one of those rare men in whom advancing years diminish neither the capacity for work nor the power of leadership. Only recently elected to preside over the State Society, he had shown during the few months of his administration the same high efficiency and sterling character that had distinguished his long professional career. He brought to this office a ripe experience and an executive skill that he had already displayed as head of his County Society, and as chairman of its legislative committee. With a keen vigilance he had scrutinized the numerous projects of medical legislation, and had stoutly championed the cause of the profession, both in the committee room at Albany and on the floor of his parent society. He died fighting in the vanguard of the battle for elevating the standards and conserving the interests of the profession. This aspect of his career formed a fitting complement to his eminent activities as practitioner, scientist, and teacher. His numerous contributions to obstetrics and gynecology placed him among those whose achievements in these branches have shed lustre upon American practice. As an appropriate eulogy one may apply to Dr. Jewett the very words with which he greeted the venerable Jacobi in the recent celebration of the latter's birthday: "Most of all at this time are we mindful of your long and distinguished service in the Medical Society of the State, not alone through the unique value of your many contributions to its scientific work but as well by your ever helpful counsels in shaping its policy and in furthering its highest aims, and no less by your lofty example of professional character and good citizenship. We are keenly sensible how much your learning and achievements have contributed to the proud position we hold in American medicine."

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CANCER RESEARCH: A STATESMAN'S REVIEW—CARE AND CONTROL OF FEEBLE MINDED—BRITISH MEDICAL ASSOCIATION—ROYAL INSTITUTE OF PUBLIC HEALTH—CAFFEINE AND THEOBROMINE—QUEEN ALEXANDRA'S SANATORIUM—OBITUARY.

LONDON, July 22, 1910.

At the Royal College of Surgeons, on Wednesday, Mr. Balfour, vice-president of the Imperial Cancer Research Fund, presided over the annual meeting. Though he modestly said that everyone he was addressing was more competent to say something to him than he was to them, it might not be without value for an outsider and a layman to give his impressions of the work done and being done by the Fund. I think your readers will be interested in his impressions, for no outsider is more competent, if so competent, to submit the views of scientists to searching philosophical examination. He has strong proclivities toward scientific study and knows the difficulties that surround research, can appreciate the most delicate investigations and present their results in a manner at once exact, precise, and charming.

The report of the year was moved by Sir Wm. Church, who said it had been largely devoted to immunization and breeding experiments. Prof. Sims Woodhead seconded and said if no great advances had been made many important questions had been tackled, as those who read the report "from the inside" must acknowledge.

Then came the distinguished "outsider" with a vote of thanks to the committee.

Mr. Balfour said it was seven years since he took the chair and he thought much had been done in that time. Considering the enormous class of diseases now known to be due to microbic invasion, progress was not to be made by accidental discoveries but to that broad scientific outlook which has produced unexpected results in every field apart even from human pathology. Who could have expected, he continued, within the lifetime of myself and others listening, that we should see some sort of common course in such utterly different things as the production of alcohol, of pearls and of whooping cough? Yet our knowledge of these different things has come about by investigations into the actions of microscopic organisms. The public ought to know that all that has been done in tropical medicine, in vaccine therapy, all the triumphs won and the greater triumphs which are going to be won, are based upon this broad investigation into great scientific issues. I gather, he said, that the results of the Fund's work go to show that while ordinary infectious diseases are due to external invasion, tumors are due to domestic rebellion, and so are entirely different in their causes. Two important generalizations appeal to me strongly. One is with regard to heredity, as to which it is impossible to draw conclusions without observation on short lived animals. I gather that systematic work with these enables our staff to conclude that heredity in connection with cancer is almost negligible. If so, these malignant tumors are not innate in the organism at birth, and the researches of the Fund go to show that there are undoubtedly causes which produce cancer even in the best behaved tissues, even in tissues which, in people leading normal lives, scarcely ever show malignant growths. Well, surely that indicates that something may be done to prevent or diminish cancerous growth. I do not wish to put it in the least too high. I know Dr. Bashford is listening with nervous anxiety lest I give too sanguine a view of his conclusions. I wish to put it in the most cautious way, but even Dr. Bashford, with all his caution, will not deny that our Fund's investigations into the manner in which chronic irritation produces cancer may enable us to diminish the causes by which it may be produced.

As to the problem of how malignant growths, when present, have to be dealt with, it would be cruel kindness to suggest that we are within sight of anything that can be called a new remedy. But surely we may draw encouragement from researches which show that the growth and spread of implanted cancer can be checked. No experiments have given the same results with original tumors. But I think it is difficult to doubt that the difference between original and implanted growth is only of degree—not of kind——and therefore not too sanguine to say we need not abandon hope by further researches of becoming able to deal with the more refractory original form. That is how it strikes the lay mind, and I hope Dr. Bashford will not think I have gone too far in indicating hopes I entertain, though whether I may live to see them bear fruit I cannot say. If that is not an overstatement of the case let no man think because our work is so extensive, its foundation laid on the broadest base of scientific experiment, that it is other than the only possible method which is going to produce results for the good of humanity.

The care and control of the feeble-minded has of late been a subject of much discussion, both within and without the profession. Besides the efforts of the voluntary institutions and meetings connected with them, we have had a deputation to the government and a conference of persons interested in defectives, at both of which the proposal of the Royal Commission to set up a central authority was supported by many advocates of such control, though others offered important criticism. Dr. H. B. Donkin favored the new board recommended by the Royal Commission, provided its constitution be predominantly medical, as its work would be of that nature and certification and inspection of institutions could only be properly entrusted to highly qualified and experienced medical men.

Various speakers pointed out that the several authorities at present concerned with defectives often differed in their views and should therefore be consolidated or superseded. Most of them seemed inclined to regard the lunacy commissioners as best able to deal intelligently with the problem.

Dr. Mercier, whose authority as an alienist is second to none, was for caution and remarked that though he was generally in a minority of one, he deplored the tendency of modern legislation to coop up the population in institutions. He rather thought some should be left out if only to turn the key on the others. The certificate framed by the royal commission was such that almost any one could be brought under it. The burden of too many institutions might become intolerable, and there was further danger in breaking up home life and permanently detaining the weaker members of a family on whom the most devotion was often lavished. Dr. Mercier's warning was not altogether unappreciated.

At the deputation to the government the Lord Chancellor expressed an opinion which to a considerable degree coincided with Dr. Mercier's. He regarded the phrases as to control and detention as identical and said the difficulty of deciding when such could be applied deeply concerned the administration of the Lunacy Laws, for nothing could be more fatal to the object of protecting the defective than the misapplication of the powers of control. Mr. Burns, too, told the deputation whether they wished so or not they were practically working for such compulsory control as was now exercised over adult lunatics; of course, with safeguards to prevent abuse. Detention meant more institutions and other costly changes which no government could give unless public opinion was decided in its favor. He had hoped to hear something about the causation of feeble-mindedness.

The seventy-eighth annual meeting of the British Medical Association, which is to occupy all next week, practically begins to-day, with certain official proceedings which do not concern the profession generally. For the opening, a general meeting and an extraordinary general meeting to follow, as well as a meeting of the representatives, have been fixed, after which the councillors and representatives are to dine together.

Many provincial members are already in town, taking the opportunity of visiting friends, their old hospitals and other medical institutions, at almost all of which special arrangements are made to show their most interesting work and otherwise welcome their visitors.

Of course, considerable advance has been made with the museum of medical, surgical and sanitary instruments and appliances, as well as drugs, books, etc., which is usually held, but it will not be opened until Monday. In connection with this x-ray and high frequency apparatus will be shown. In the medical department the specimens illustrating the papers read in the various sections form an important display, particularly in reference to tropical medicine, protozoology, etc. These and the business meetings will fill up the time on Monday and Tuesday. On the evening of the last-named the president's address, always an interesting event, will be delivered, and on the succeeding days the sections will be at work and your reporters will supply you with some of the chief discussions.

The Royal Institute of Public Health is this week holding its annual congress. Birkenhead is the place of meeting this year and the president, Mr. Lever, gave an inaugural address in which he pointed out that the sphere of the institute's activity is not limited to sanitation, but every fact and circumstance affecting home life and bodily and mental health came within the field of their study and research. Side by side with researches into the courses of ill health, decay and death of the body he would place research into the everyday life of people engaged in the rush of business as affecting body and mind.

Caffeine is commonly regarded, I believe, as a stronger alkaloid than theobromine; at any rate coffee is thought to be a more stimulating beverage than cocoa. A paper contributed to the Royal Society by Drs. Veley and Waller points in the other direction. By measurements of the contractility of isolated muscle, they find the toxicity of theobromine greater than that of caffeine in the proportion of 3 to 2. The effects of the extracts of tea and coffee were also studied, the conclusion arrived at being that they were due to the contained caffeine and not to tannin.

Queen Alexandra's Sanatorium at Davos has been opened free of debt and has now six months' successful work to its credit. This is the report submitted to the supporters on the 15th at the meeting held in the hall of the Medical Society of London. There are 54 beds for patients. From the date of opening (November 15) to March 31 there were said to have been over 7,000 patients' days." The receipts amounted to £43,130, and there was a balance of £5,277 to the good. But a shortage was in prospect on the income and expenditure account. Princess Christian became a vice-patron, and Sir T. Barlow, F.R.C.P., has joined the council.

Inspector-General R. Grant (R. N., retired) died on the 14th inst. at the age of 68. He took M.A., Aberdeen in 1863, and M.B.C.M., 1866, and entered the Navy in 1868. He served on shore in the Kaffir War, 1877, was specially promoted for services in charge of smallpox patients on the Boadicea, and as staff surgeon landed during the Zulu war accompanying the naval brigade to Fort Durnford, for which he was awarded the medal as he was also in the Egyptian War, 1882, together with the Khedive's star. In the Eastern Soudan in 1884 he accompanied the Royal Marine batallion in action; was again mentioned in despatches and received medal and clasp. In 1901 he retired as Inspector-General, receiving the C.B., and became a magistrate and deputy-lieutenant for Banffshire.

Lieutenant-Colonel Walter Conry, late of the Bengal Medical Service, has died at the age of 61. He took the diplomas of the two Edinburgh Royal Colleges in 1875, the M.B.Dub. next year, and joined the Indian Medical Service in 1877. He went through the Burmese Expedition in 1885-7, for which he held the medal and clasp.

OUR BERLIN LETTER.

EHRLICH'S NEW SPECIFIC FOR SYPHILIS.

BERLIN, July 20, 1910.

PAUL EHRLICH is doubtless the German physician upon whom the interest of many more than his own colleagues is concentrated, for the knowledge of his pioneer labors has penetrated through the lay press to the general public, who follow his work with the highest degree of interest. I have already had occasion in my letters to speak of Ehrlich's method of work, in a representation of his lecture on specific therapy. From the commencement of his labors Ehrlich has had in his eye the design of annihilating at a blow the living causes of disease in the body—the "therapia sterilisans magna." It appears that the efforts of himself and his collaborator, Hata, have been successful in the case of syphilis. The remedy, to which he has given the name of "Hata-preparation," is an arsenical body—dichlorhydrate-dioxyamido arsenobenzol—a light yellow powder, which is applied in a 0.5 to 2 per cent. solution. An injection should consist of 0.3 gm. of this substance plus 0.8 gm. arsenophenylglycin.

At the end of June a discussion took place in the Berlin Medical Society at the close of a lecture by Wechselmann on the treatment of syphilis with this preparation. Patients were presented, and the brilliant results of treatment were admitted on all sides. The lecturer regarded the preparation as a specific for syphilis. A series of patients in the florid stage of disease was presented; they had received but a single injection and in all manifestations of disease had vanished in from 8 to 14 days. Patients were shown who had been treated in vain with mercury, and recovery had also been obtained in chronic cases. Syphilis maligna and visceral syphilis likewise yielded fully to this treatment. With insufficient dosage recovery did not take place. The dose must be so measured that even by the second day spirochetes are no longer found. The Wassermann reaction gradually disappears as the treatment progresses. The excretion of the remedy is completed by the third day. Thus far no toxic symptoms have been noted in adults. In animal experiments no affection of the optic nerve had been observed. Nurslings may be temporarily damaged as a result of the liberation of endotoxins upon the death of the spirochetes.

In the discussion L. Michaelis reported two cases, one of which had been treated without success by all the older remedies, while the other was oversensitive to mercury. Both recovered under a single injection of the new arsenical preparations. He presented a child with infiltration of the palms and soles and an exanthem. It received a single injection and all symptoms vanished within eight days. Alt, who was the first to use the new arsenical preparations in man, mentioned the difficulty at that period of testing arsenical compounds on mankind, by reason of bad reports. The labor itself was simple, as Ehrlich had already worked out fully all the details. First, at his institution for mental diseases arsenophenylglycin was injected, and an alteration in the lecithin metabolism, likewise a disappearance of the Wassermann reaction, determined. The remedies may be injected intragluteally as well as intravenously. By the first named method absorption is delayed, while this is not the case if the latter is used. Very notable improvement was obtained in tabes and paresis. Also cases of epilepsy on a syphilitic basis were favorably influenced.

Schreiber of Magdeburg had seen good results in severe cases of syphilis. Among 128 cases there were but 10 which showed a relapse inside of four weeks. In these cases the dosage had been insufficient. The speaker had never seen an unfavorable result. He preferred the intravenous to the intramuscular injection. An alleged death from the treatment reported in the daily press was a pure invention.

Ehrlich, who had hurried from Frankfurt to be present, now took the floor, amid great applause. The credit for the good results, he said, should be ascribed not to him, but to the practitioners who had used the remedies. Certainly it is difficult to discover a good remedy, but it is just as difficult to apply one in practice. Only continued application will reveal the best method for injecting it, whether intramuscular or intravenous. Thus far the following preparations have proved themselves the best: For intramuscular injection the new arsenical compound should be dissolved in a graduated tube in 3 c.c. glycol, stirring with a glass rod being used to aid in solution. The addition of a few drops of water also aids solution. The latter is now shaken with 12 c.c. water, and to the whole is then added, all at once, 10.3 c.c. normal one-fifth sodium lye. Upon shaking a clear fluid is produced, to which 60 c.c. water is added. For intravenous injection two solutions are prepared. Solution A consists of 0.6 gm. of the new preparation, 0.3-0.5 c.c. methyl alcohol (or 3 c.c. glycol). Solution B consists of 240 c.c. physiological saline solution or upward, and 10.3 c.c. normal one-fifth sodium lye. Solution A is then poured into solution B, the whole being well stirred the while.

Kromayer had treated 15 cases with success, cases in which mercury had failed to cure. It appeared that epithelization had been powerfully promoted by the remedy. One severe case of psoriasis had yielded almost completely to the remedy.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 28, 1910.

Nephritis Without Albumin.—C. A. Howland endeavors to show that gross and severe lesions of the kidney may exist without albumin being present in the urine or at least without it being discernible by methods ordinarily used in hospital and office work. In the routine examination of 550 specimens of urine, nephritis without albumin was found 21 times, or 3.8 per cent. The writer gives the history of these 21 cases, and concludes that no examination of the urine can be called thorough unless a microscopical examination is made. This cannot be satisfactorily done unless the urine is centrifuged in a good centrifuge. No physician can be sure that his patient is free from a kidney lesion without such an examination. Acute nephritis may exist without the presence of albumin, and death may occur with all the symptoms of uremia. Care-

ful pathological study of kidney tissue, when during life acute nephritis without albumin has been diagnosed, may reveal a distinct type of hitherto unrecognized nephritis. The fact that nephritis may accompany other severe diseased conditions does not lessen its importance. The knowledge of its existence will to a great degree influence the treatment and prognosis.

The Sputum of Typhoid Fever Cases as a Possible Source of Infection.—Elmer S. Tenney reviews the literature on this subject, from which one derives the impression that the bacillus typhosus is not frequently to be found in the mouth, and that it may be, but usually is not, the cause of pneumonia complicating typhoid fever. He describes the technique which he used in his experiments, and summarizes as follows: In a study of the saliva and sputum of 53 cases of typhoid fever, several of which showed bronchial symptoms, but none pneumonia or any laryngeal complications, the bacillus was not found by means of the technique employed. Typhoid bacillus will live for at least 125 days in the saliva and sputum, and can be readily transplanted from one specimen of such material to another and kept growing in it at room temperature for a long time. In view of the reported finding of the bacillus in cases complicated by pneumonia and by laryngeal inflammation, it would seem that more work should be done along the lines followed in this series. While the sputum does not frequently contain the typhoid bacillus, it does so occasionally, and on that account it cannot be ignored as a source of infection.

New York Medical Journal, July 30, 1910.

Spondylitis Deformans.—Antonio M. Crispin reports this case which he believes is the only one thus far reported occurring in the dorsal vertebræ and presenting the unusual symptoms herein observed. This case is a man 53 years of age who was struck in the back with a stone three years ago. He experienced no inconvenience at the time, but a year later began to suffer pain in his back and consulted a physician. Later he came under the writer's observation, complaining of pains over the chest and back excruciating in nature. Examination revealed an angular deformity of the rhachis, at the level of the seventh and eighth vertebræ. The spine was rigid and the gait of a peculiar shuffling character. The heart was slightly hypertrophied with slight accentuation of the second aortic sound. The thorax was flattened anteroposteriorly, due to the kyphosis. The epitrochlear glands were somewhat enlarged. Knee reflexes were greatly exaggerated, ankle clonus very marked and other reflexes were also present. There was no muscular atrophy, but impairment of motion with fear of falling. The muscular sense was retained. Paresis was more noticeable on the left leg with a small area of tactile anesthesia in the upper part of the thigh with some rigidity. Thermoanesthesia and analgesia were noted on the right side below the eighth dorsal vertebræ with normal motion, slightly constrained. There was a circumscribed zone of anesthesia on the outer side of the thigh and above all a hyperesthetic band. The location of the lesion in this case seems to uphold the conclusion reached by Brissaud that Gower's tracts are the conductors of pain and temperature, and lends support to the clinical evidence that lesions of the upper dorsal region are productive of an excessive lowering of the temperature and pulse. The writer urges the importance of the early recognition of pressure symptoms which constitute a formal indication for surgical intervention, which must be undertaken before complete degeneration of the cord results. For the relief of pressure symptoms he recommends rest and mechanical appliances. When the compression of the cord is marked resection of the vertebral arch is indicated. Two other cases of spondylitis which he had seen did not have the Brown-Sequard syndrome which was present in this case.

A Method of Anesthetizing to Be Employed in Operating on the Aged.—John H. Gleason, led by the effects that were observed when scopolamine combined with morphine was used before the administration of a general anesthetic, began experimenting with this agent and conceived the idea of combining partial scopolamine anesthesia with local anesthesia, using 0.1 per cent. cocaine. This proved so successful that he began using scopolamine anesthesia in operating upon the aged. Satisfactory results are dependent upon the technique; the operator must be thoroughly familiar with anatomy in order that the nerves may be blocked by depositing the water around and close to them. He usually administers 0.01 grain of scopolamine with 1/6 to ¼ grain of morphine, and repeats the dose at the end of an hour. The dose is varied according to the condition of the patient. The writer cites a number of cases in persons over eighty years of age in whom he has used this method successfully, and urges its adoption in the management of surgical diseases in old people. Realizing the danger that may result from heart, lung, kidney, or bladder complications in these cases, they are often classed as inoperable. This is a mistake when we have this safe and accurate method which permits the patient to take nourishment regularly and enables him to avoid functional disturbances of the stomach and other organs.

Does Internal Medicine Tend to Abort or Cure Abscess and the Tendency Thereto.—Robert E. Coughlin believes that if individuals predisposed at all times to the development of abscess were examined carefully at different times when supposed to be in a condition of health they would undoubtedly show some abnormality in their makeup that would give some light on the etiology and predisposing factors. Abscess of the appendix may be anticipated by attention to the etiological factors. The use of serum to produce immunity in typhoid and the antiseptic treatment of the disease may prevent extension into the gall bladder and a subsequent abscess. Internal medication in the case of pyelitis may abort a suppurating kidney. Internal medication in a case of dysentery, malaria, or tropical fever may prevent a liver abscess. Vaccines have been used with some success in pyemia, pyosalpinx, and tuboovarian abscess by indicating opsonins, etc. Following out this line of reasoning abscesses of the skin, boils, furuncles, furunculosis, and carbuncle are due to a disordered condition of the system, and in the latter staphylococcus serum has worked well along with supporting treatment; as, for instance, strychnine as a stimulant with opium to relieve pain. Calcium sulphide is effective in modifying all suppurative processes in a most decided manner, the dose used being one-half to one grain three times daily in adults and for children one-tenth to one-twentieth of a grain three times a day. When indications have been carried out in the manner suggested one cannot fail to be convinced that internal medication does tend to abort or cure abscess.

Journal of the American Medical Association, July 30, 1910.

Treatment of Localized Appendicular Abscess.—Van Buren Knott discusses the question as to whether the surgeon should or should not remove the appendix in practically every case of localized appendicular abscess. During the past two years he has operated upon 161 cases of sharply localized appendicular abscess, and in every instance has removed the appendix at the first operation, whether it could be easily detected in the abscess cavity or whether deeply buried by adhesions. The mortality was 1.4 per cent. Drainage of the larger pus collection does not reach smaller hidden septic foci. As to the technique the author makes the incision through the right rectus muscle, splitting the fibers and opening the peritoneal cavity freely. Small packs are used to prevent extravasation. The appendix is exposed and removed after mopping away pus with gauze sponges. All adhesions separating the abscess cavity from the lower pelvis are freely separated, pus removed, and drainage instituted by means of a large split rubber tube from one-half to one inch in diameter and carrying a wick of iodoform gauze which is inserted through the lower angle of the wound to the bottom of the rectovesical pouch or cul-de-sac. The protecting gauze is removed and the wound closed down to the tube. The writer urges the more frequent use of this form of drainage by competent surgeons and thinks that the instances in which it is contraindicated are rare. The appendix should be removed at the first operation rather than subject the patient to a prolonged and serious secondary operation.

Cryptophthalmia.—David H. Coover describes this condition as usually found and reports two cases. The first in a woman twenty-four years of age is otherwise perfectly developed. There is an indication of the palpebral fissure in the form of a shallow depression corresponding to the curvature of the lids. Well-formed eyebrows are present. About midway between the lower margins of the upper lids and the margins of the orbits are two rows of hairs. At these points there are slight depressions in the lids. The patient gives a history of light impression at an early age. There is no history to which any congenital defect can be traced. The woman married a man who had lost his sight and a child was born which is the exact duplicate of the mother. The right eye was chosen for operation. There was complete symblepharon. Retracting the lids and inserting a finger a small eyeball could be felt and on dissecting away the tissue an imperfect eyeball was exposed. A small point brought into view had the appearance of corneal tissue. No extrinsic eye

muscles could be detected macroscopically, but the presence of an optic nerve was determined. The sclerotic was accidentally snipped and some vitreous fluid escaped. There was no possibility of vision.

The Action of Alcohol on the Normal Intact Unanesthetized Animal.—After reviewing his methods of connecting the manometer with the blood-vessels without pain to the animal and therefore without need of an anesthetic Clyde Brooks reports concerning a series of blood-pressure tracings showing the effect of alcohol on an animal not under the influence of an anesthetic. The alcohol was administered by three different modes, namely, by mouth, by intravenous injection, and by gastric fistula. The primary action of alcohol varies according to the mode of administration. By mouth it causes a marked rise of blood pressure with increased amplitude and a constant, or slightly slowed, rhythm of heart beat. This rise gradually passes off in five or ten minutes. In some instances at the time of pouring the alcohol into the dog's throat there is a sudden drop and almost immediate recovery of blood pressure. When administered intravenously, it causes a sharp drop in blood pressure, during which the heart is greatly slowed or almost stopped; very soon, unless the dose is too large, recovery follows. By gastric fistula there is no specific primary action. By whatever method administered, alcohol, when circulating in the blood stream, causes a gradual, progressive lowering of the blood pressure, with decrease of amplitude, but increase in rate of the heart beat.

The Danger of Sympathetic Ophthalmia from the Use of the Cautery in Treating Iris Prolapse.—H. Gifford recalls the histories of ten cases of sympathetic ophthalmia in which the authors mention incidentally that a wound or an iris prolapse had been cauterized a suitable length of time before the outbreak of the disease in the other eye. He then reports a similar case in his own experience and summarizes his views as follows: (1) Fresh non-infected prolapses should be replaced if possible; preferably by Dunn's method. (2) Prolapse which cannot be cleanly excised should, if possible, be cauterized and the area scraped and protected at once by a conjunctival flap. (3) On account of the danger of sympathetic ophthalmia, no prolapse should be treated by a hot metal cautery, unless a protecting conjunctival flap can be made to adhere to the area to be cauterized; it is probably safer to let the prolapse alone. (4) In some cases of large corneal prolapses to which conjunctival flaps can be made to adhere with difficulty, or not at all, the use of trichloracetic acid (and probably of various other chemicals) produces a firm non-irritable scar. Whether this method is entirely devoid of danger remains to be seen.

Serum Treatment of Hemorrhagic Disease of the New Born.—Edward B. Bigelow believes that the lack or modification in some manner of the fibrin ferment, as in Weil's explanation of hemophilia, is often a factor and the possible cause of this disease. He reports three cases which were treated with injections of clear rabbit serum, 5 c.c. of the serum being injected immediately after securing it from the animal and a second injection being given later. Two of these patients were apparently moribund when the serum was administered. The other case had not progressed so far, but was in a serious condition, for previous to the injection the bowels had moved each hour for nine hours, with large results of dark, tarry, meconium-like material and bright red blood, and on the sixth day the baby weighed 24 ounces less than at birth. Although the condition is self-limited in 25 per cent. of the cases, the sequence of three recoveries in serious cases should be ascribed to the action of the serum. The most impressive fact in each case was the almost immediate control of the hemorrhage after administering the serum. This was shown directly by observation of the umbilicus in the first case and the nose in the third, and, indirectly, in all three by the condition of the stools. The serum gave absolutely no untoward effects in these cases. Serum treatment has a distinct place in the therapy of this condition because of its simplicity and the lack of operative shock attendant upon transfusion.

The Lancet, July 23, 1910.

A Case of Dermatomyositis Ending in Recovery.—N. C. Gwynn and W. Gordon report this case because of the rarity of this affection, there being only about thirty cases reported in literature. The patient was an officer in the Indian Army, aged fifty years, in whom the onset and course of the disease and the grouping of symptoms left no reasonable doubt as to the diagnosis. Trichiniasis was ruled out by the grouping of the symptoms, the fact that there was no ascertainable source of that disease, the absence of considerable eosinophilia, and the absence of trichinæ from the stools. As is usual in dermatomyositis, no culture could be made from the blood, and the case throws no light on the etiology of the disease. The clinical picture suggested a toxemia arising from some infection of the alimentary canal, and efforts were directed to disinfection of the mouth, throat, stomach, and bowels. There was no doubt but that the mouth symptoms responded to the treatment, and there is reason to believe that the rest of the alimentary canal was benefited because of the marked improvement and ultimate recovery from an extremely grave condition.

An Examination of the Blood Serum of Idiots by the Wassermann Reaction.—H. R. Dean gives the results of the Wassermann test in 330 idiots of the Wilhelmstift Asylum at Potsdam. Of these 330 cases 51, or 15.4 per cent., gave a positive reaction, but only seven showed conclusive evidence of congenital syphilis from a clinical standpoint. Among 13 parents of these children 9 gave a positive reaction. In an examination of the cerebrospinal fluid from 12 cases which had given a positive serum reaction a positive reaction was obtained in only one case. The tests seemed to show that the percentage of positive results diminishes rapidly after the sixteenth year, and that a larger percentage of positive results might be expected from the examination of a series of very young cases. A careful examination of the cases giving a positive reaction failed to show any symptom or group of symptoms common to all. It seems reasonable to think that many cases of idiocy should be classed with that form of syphilis which manifests itself alone by a selective toxic action on the elements of the central nervous system. When it can be shown that a considerable percentage of idiots afford evidence of syphilitic infection, and since it is well known that the virus of syphilis is capable of exercising a selective action on the central nervous system in cases in which there is no other evidence of the disease, it is not unreasonable to infer a causal relation between the two conditions.

Tuberculosis in Its Relation to the Generative Functions.—James T. R. Davison makes a study of the mortality from tuberculosis in Buenos Aires which confirms the fact that youth is not the period of predilection for this disease. The table shows that tuberculous mortality reaches its highest level in the case of Argentine men from 20 years upwards, especially between 30 and 60 years of age. In the case of Argentine women the highest level of tuberculous mortality obtains between 15 and 50 years of age, but especially between 20 and 40 years. These epochs of life correspond to those in which the generative functions are most active in each sex. The low levels of mortality correspond to the ages of infancy and childhood in both sexes, and to the period after the menopause in the female. The high level corresponds to maturity and advanced age in the male and only to maturity in the female; that is to say, the high level corresponds to the periods of greatest sexual activity in both sexes. The generative functions require a great expenditure of nervous force, and thus tend to lower resisting power, and Koch's bacillus is consequently not so well resisted.

Notes on the Treatment of Rheumatism by Bee Stings.—F. H. Maberly relates his experience with a number of severe cases of rheumatism which refused to respond to any of the usual methods of treatment and in which bee stings gave relief. In elderly people he starts with about six stings for the first three applications and then increases the number gradually up to a couple of dozen. The stings should remain in for a few minutes before removing them. He concludes from his experience that this remedy, if it does not effect a complete cure, gives relief in almost hopeless cases.

British Medical Journal, July 23, 1910.

Tubercle Bacilli in the Feces in Tuberculosis.—R. W. Philip and Agnes Ellen Porter, after describing the technique which they employed in their examinations, summarize their results as follows: Of 100 specimens examined 99 were from patients suffering from pulmonary tuberculosis, and none had intestinal tuberculosis. The remainder had no suspicion of tuberculosis with the exception of one case of tuberculous peritonitis. Of these 100 persons only 34 had sputum in which the tubercle bacilli were found, 24 had sputum in which no bacilli were found, and 24 had no sputum. The feces of the 100 tuberculous cases yielded tubercle bacilli in 70 instances. Of the nine specimens from presumably normal subjects none yielded tubercle bacilli. All the tuberculous patients whose expectoration showed bacilli presented tubercle bacilli in the feces also. Of 42 cases in which bacillary examination of the sputum was negative, 20 gave tubercle bacilli in the feces.

Of the 24 cases without sputum 17 showed bacilli in the feces. Thus it may be stated with absolute certainty that the occurrence of tubercle bacilli in the feces is independent of the presence of an intestinal lesion. The bacilli were actually absent in the case of tubercular peritonitis. The remarkable frequency of their occurrence in relation to pulmonary tuberculosis would seem to afford an important addition to our means of diagnosis in doubtful cases of that condition. Even where swallowing of the sputum was carefully guarded against the tubercle bacilli were constantly found in the stools. These findings raise the question of the need of disinfecting stools.

Scarlatina Maligna.—Arnold Gregory believes that the malignant and toxic form of scarlet fever is rarely met with nowadays, and that such cases are sufficiently rare to justify their publication. He relates that a few days after the development of a case of scarlatina in a family of seven children a second child became very ill with vomiting, diarrhea, and abdominal pain. A temperature of 104, rapid, weak pulse, and great delirium followed, and the child died forty-eight hours from the time of the onset. The day following that upon which this child had been attacked a third child suddenly became ill with similar symptoms. Recovery seemed impossible, but he finally improved; rash appeared in this case four days after the onset of the illness. A fourth child was attacked in the same way as these two, and died at the end of thirty-eight hours after the onset of his illness. Two other children suffered from typical attacks of scarlatina. No eruption appeared in the two cases that succumbed, probably because of their early death. In regard to the proportion of cases of malignant scarlet fever to the total number of cases statistics are of comparatively little value, for most of the toxic cases succumb before it is possible to make the diagnosis. The writer considers the part that family susceptibility plays in regard to infection and refers to the fact that susceptibility is less after puberty.

Recurrent Monstrosity.—E. Napier Burnett reports the case of a woman thirty-five years of age who gave birth to a healthy male child. A second pregnancy ended in an abortion at the end of the third month; the fetus was anencephalic. The third pregnancy ended in an abortion at the end of the fifth month, this fetus being also anencephalic. The fourth pregnancy concluded at term. Labor being delayed, the writer incised a presenting mass which he supposed was a tumor and emptied out a large quantity of brain tissue, which showed both cerebral and cerebellar structure. He then reached the cranial vault and what appeared to be a normal cranial cavity. The child was of female sex, with large shoulders and short neck, eyes protruding, and nose flattened. There was little liquor amnii. The child lived about a half hour after delivery. The cephalocele was situated in the usual position for such tumors. Cephaloceles are comparatively rare, Trelat being quoted as having had three cases in 12,900 labors, and in his series of 325 specimens of antenatal deformity there are only eight cases of cephalocele, in contrast with 46 of anencephaly. In this case there was nothing whatever that would account for this condition.

Turpentine Enemata in the Treatment of Enteric Fever.—W. J. J. Arnold urges the importance of early recognition of this disease, the value of skilled nursing, regulation of diet, and attention to oral hygiene, and recommends a measure which he has employed for the past four or five years which results in a distinct shortening of the average duration of the illness and a remarkable ameliora tion of all symptoms. This measure consists in the administration, by the bowel, of an enema of one ounce of turpentine to one pint of olive oil given by a funnel and tube when the case first comes under observation and after a preliminary dose of calomel and castor oil. On the following day or the day after the quantities are repeated. The quantities may then be reduced to one-half ounce of turpentine to fifteen ounces of oil administered on alternate days throughout the course of the disease and continued until convalescence is fairly established. This method enables one to treat the disease with a confidence that other methods fail to impart.

A Fatal Case of Hemophilia.—L. A. Parry relates the case of a boy, four years of age, who bled very freely from a cut about one-third of an inch in length on the front of the right side of his tongue. Stitching the edges of the wound together did not stop the bleeding. The cut ends of the blood-vessels were then caught with forceps, which lessened the bleeding, but on putting in two more stitches free oozing took place from the needle punctures and continued uninterruptedly until a few hours before death, which occurred about forty-eight hours after he had first seen the patient. Calcium chloride was given in large doses. The child had nearly bled to death on a previous occasion from a small cut on the finger. This case illustrates the well-known facts that the tendency to hemophilia usually appears early in life, the first hemorrhage rarely kills, and over 50 per cent. of those thus affected die before the age of seven years.

Artificial Respiration in New Born Infants.—W. E. Fothergill considers the Shultze method of artificial respiration both dirty and risky, and says that he has used and taught the Buist method for many years and has found it effective, clean, and free from risk, and it can be continued for a long time without causing fatigue. The child is placed face downward on the palm of the hand with the head away from the operator. The upper and lower parts of the body and limbs are thus dependent over the edges of the hand. The child is then rolled over and at the same time transferred with a slight throw to the right hand in the dorsal position, the legs and arms being again dependent. It is then transferred to the left hand in the first position and the movement repeated twelve to sixteen times a minute.

Dislocation of the Neck During Sleep.—Douglas E. Derby writes that while in Nubia, in connection with the Archæological Survey, a native boy, eight years of age, was brought to him whose head was tilted to the right side and rotated in the same direction. Any attempt to turn the head was accompanied by pain; muscles on the left side of the back of the neck were extremely tender, and there was a definite lump slightly to the left of the middle line which appeared to be contracted muscles. The father said it might have come on during sleep. Three weeks later, having read a paper on the subject in the meantime by F. M. Sherman, he put the boy under an anesthetic and had him held while he pulled strongly and steadily backwards, keeping the head still in the twisted position, and then rotated it into the middle line, as described in Dr. Sherman's article. The lump entirely disappeared, and the head could be easily turned to the left. The patient no longer complained of pain when the originally painful muscles were palpated.

Berliner klinische Wochenschrift, July 11, 1910.

Results of Serotherapy of Diphtheria in Amsterdam.—Timmer presents a number of tables which show the mortality of diphtheria before and after the serum period, with the incidence and mortality of operative cases. The number of deaths between 1890 and 1894, inclusive, was almost exactly the same as that between 1895 and 1908, inclusive. In other words, the number of deaths for five years (411) before serotherapy coincided practically with that (409) during fourteen years of serotherapy. The corresponding percentages are 37.8 under the old and 9.7 under the new régime. The highest annual death percentage under serum was 12, lowest 3.5. Highest annual percentage of preserum period 45, lowest 30. In the five last years of the preserum period 55.5 per cent. of all patients came to operation (tracheotomy and intubation); while in the fourteen years of serotherapy but 29 per cent. required surgical intervention. The material for these statistics comes entirely from two children's hospitals. It is of interest to note that the mortality figures of the two institutions differ somewhat in respect to operative cases, *i.e.* a high mortality in one hospital for a given year was sometimes offset by a low one in the other. In the Emma Children's Hospital deaths in intubated (and tracheotomized) cases varied from 14 to 40 per cent., and in the Wilhelmina Gasthaus the limits of variation were nearly the same. Further, it is apparent that there has been little change in the death rates of operative cases since the favorable influence of serotherapy was first exerted in 1895. The author is forced to conclude that the higher mortality in one hospital for a given year can only be explained (in conformity with hospital figures in general) by the fact that certain institutions are bound to get the worst cases at certain periods. In 1906 the total death rate of diphtheria for both institutions was 10.2; yet in this year the mortality of operated cases in the Emma Hospital reached 40 per cent.

Lipoidemia.—Adler, who has already written on this subject, has examined the blood in various diseases as to its lecithin and cholesterin content, and both in natural and experimental disease. He finds a connection between lipoidemia and acidosis, irrespective of whether the latter is diabetic or non-diabetic. From animal experiment he generalizes as follows: In acidosis with glycosuria, the blood is notably richer than normal in cholesterin, and correspondingly poorer in lecithin. On the other hand, in acidosis without glycosuria we have a lipoidemia of the Klemperer type, *i.e.* both cholesterin and lecithin show increase.

Arabinosuria.—Schüler, who has studied the nature of pentosuria for a number of years, in the attempt to assign to it some clinical significance, has found that in certain cases of this condition the pentose has been present chiefly as dextrorotatory arabinose, although in most cases the pentose has not been optically active. In regard to the significance of pentosuria, this may be purely alimentary, but the author was never able to find arabinose in the urine after feeding with substances containing the pentosans. The patient with arabinosuria also had orthostatic albuminuria, and both disappeared at the same time. Attempts have been made to show that pentosuria indicates an anomaly of metabolism. The author discredits this view. He thinks there is enough clinical evidence to show that it may be due to a temporary functional disorder of the nervous system. The amounts of pentose formed are too trifling to justify any comparison with glycosuria as a disorder of metabolism, although patients with pentosuria have been found in diabetic families. There is no reason for supposing that special significance attaches to special forms of pentose in the urine.

Münchener medizinische Wochenschrift, July 5, 1910.

Studies in Chlorosis.—Morawitz finds that chlorosis may occur with normal or approximately normal blood count, and believes that such cases are by no means rare. They are benefited by iron just as much as cases of chlorosis with the blood count of anemia. We can no longer regard anemia as essential to chlorosis. In like manner certain symptoms of chlorosis once imputed solely to the coincident anemia—such as dysmenorrhea and retention of water—are now shown to be due to some other factor. The curative action of iron in chlorosis must be contrasted with the inutility or iron in nonchlorotic anemias. The influence of iron in chlorosis depends on some association as yet unknown.

New Theory of Narcosis.—Bürker, under this head, naturally covers the work of Overton and Meyer in speculations on this topic. It is of interest to note in passing that from the very first days of narcosis, the theory of anesthesia has borne strongly upon a supposed relationship between the fat-dissolving properties of anesthetics and the soluble fats of the brain. Soon after the discovery of ethernarcosis, this association was suggested by von Bibra and Harless, respectively. This was in 1847. Twenty years later Hermann brought up the question anew, in asserting that narcotics, besides dissolving the red corpuscles of the blood, also attacked all lipoid substances, such as protagon, lecithin, cholesterin, and fats. Nearly a generation elapsed before this subject was agitated anew by Meyer and Overton, each acting independently of the other. The joint conclusions of these authors bear chiefly on the fact that fat solvents of any character must tend to produce narcosis as a result of solution. Chemical affinity is left out of question. The general principles of the Meyer-Overton doctrine are doubtless known to all readers. Numerous distinguished biologists and chemists have from time to time sought to reconcile the crude solution theory with other known fact. Thus Verworn, Hoeber and others in equal authority have made contributions of a constructive character to the Meyer-Overton doctrine. The present author has worked along an entirely different line, to wit, electrolysis. Most of the anesthetics which have been tested biologically he has also investigated from the standpoint of electrolysis. He does not accept the physical solution theory because he finds that chemical affinity plays an important rôle in narcosis. He generalizes to the extent of stating that the greater the narcotic effect the greater the consumption of oxygen. The author's new theory of narcosis is as follows: Narcosis comes about in the first place because of lipoid solubility, which operates as it does on nerve-substance. But aside from this physical property, there is chemical affinity at work. Tissues naturally greedy for oxygen part with the latter, thereby undergoing a sort of local asphyxiation. Hence oxidation of the products of narcosis results, with acidulation of the economy, to meet which ammonia is produced for neutralization. The mobilized and decomposed fats and lipoids may appear as aceton. Narcotics are known to disturb metabolism, which they could not do as mere physical solvents. Narcosis affects metabolism as diabetes does, and hence perhaps diabetes bear narcosis very poorly.

Radium Excretion in the Urine.—Ramsauer and Caan, in connection with the injection of radioactive substances into animal organisms, note that such substances are constantly eliminated by the urine. That is to say, when a deposit of radioactive substance is made in the body, radioactive material appears indefinitely in the urinary secretion. Both blood and urine are constantly charged with emanations for an indefinite period. This problem came about naturally in response to the question "What becomes of the radioactive material so extensively used to-day in the treatment of cancer, etc." The practical bearing of this subject appears to lie in the original supposition that a radioactive substance once injected into an organism remains therein indefinitely. The authors believe that it escapes by the urine.

Deutsche medizinische Wochenschrift, July 14, 1910.

Traumatic Tuberculosis.—Kappis describes a case of severe complicated fracture of the thigh, followed by acute infectious osteomyelitis and suppuration of the knee joint, requiring amputation. The patient, although a seemingly healthy young man, had a latent apex tuberculosis, which became manifest five or six months after accident. The autopsy showed that the slight callus formed at the site of the fracture was imbedded in tuberculous granulation tissue. As the possibility of bacillary introduction from without was very slight, it was necessary to assume that the germs reached the blood from the latent focus when the latter became active, and were deposited in the seat of the injury. The acute osteomyelitis had doubtless had much to do with depressing the vitality of the patient. Death was due primarily to this and to the rapid march of the reanimated tuberculosis in the chest, secondarily to the shock of amputation.

Subcutaneous Lymphnodes in the Thorax in Pulmonary Tuberculosis.—Von Zebrowski, from numerous appended data, generalizes on this subject as follows: In about 20 per cent. of cases of tuberculosis in adults the lateral inferior thoracic lymphnodes are noticed to be enlarged in the fourth and fifth intercostal spaces at the median axillary line. This enlargement is due to the penetration of bacilli from within the thorax into the lymphnodes. The latter usually correspond to the infected side of the thorax. In a very small percentage of cases without intrathoracic symptoms these nodes may also be involved from miscellaneous diseases of other regionary organs, such as the breasts. These enlarged nodes are sometimes of diagnostic significance, as indicating a latent tuberculous focus in the chest.

Diagnosis of Duodenal Ulcer.—Günzberg, from a comparison of clinical histories with surgical and necropsy findings, and from the experience of other writers, concludes that the testimony of the patients is fairly constant in the case of duodenal ulcer, and in fact typical. There is pain two or three hours after eating, removed by taking more food. From 1 to 2 o'clock in the morning pains are often felt. These pains last for days or weeks, and are but little amenable to therapeutic efforts. This history is clinched by the occurrernce of hemorrhages—considerable losses of blood, sometimes occult blood—from the intestines. Another crucial symptom is motor disturbance as revealed by the use of a test meal—as when a von Leube meal is not disposed of in seven hours. By skillful percussion a dilated duodenum may sometimes be mapped out.

Granulation Tissue and the Gonococcus.—Klingmüller, in considering the ability of the gonococcus to produce simple granulation tissue, naturally does not refer to papillomatous growths or venereal warts, which are familiar to all. He discusses primarily certain proliferations about the anus of doubtful origin, which are distinguishable alike from hemorrhoids, pointed and flat condylomata. They are not papillomatous in structure, at least macroscopically. So distinguished an observer as Jullien describes the same perianal formations without apparently feeling free to assign them to a definite niche. The author, through the peculiar histological character, with the association of gonococci, has no hesitation in regarding them as gonococcic granulomata.

The Vascular Pathology of Congenital Syphilis.—Oscar T. Schultz says that in congenital syphilis the widespread involvement of the smallest vessels is more characteristic than the diffuse fibrosis. The primary vascular change consists of a swelling and proliferation of the endothelium and a slight lymphoid infiltration immediately around the arterioles and capillaries. It is set up by a transplantation of the treponemata from the blood stream. In the medium sized vessels there may occur in the adventitia and media an inflammatory reaction characterized by the presence of lymphocytes and young connective tissue cells. In congenital syphilis the involvement of arterioles and capillaries is more widespread than in acquired lues.—*Cleveland Medical Journal.*

Book Reviews.

A Text-Book of Nervous Diseases. By William Alden Turner, M.D. (Edin.), Fellow of the Royal College of Physicians of London; Physician to King's College Hospital and Lecturer in Neurology; Physician to Out-Patients, National Hospital for the Paralyzed and Epileptic, Queen Square, London, and Thomas Grainger Stewart, M.B. (Edin.), Member of the Royal College of Physicians, London; Assistant Physician to the West London Hospital and to the National Hospital for the Paralyzed and Epileptic, Queen Square, London. Philadelphia: P. Blakiston's Son & Co., 1910.

This is essentially a textbook for the student and general practitioner. In it may be found especially good clinical descriptions of most nervous disorders, briefly stated and with particular reference to diagnosis. The arrangement of the book and the classification of diseases are eminently practical, and follow the well-known lines of usage at the National Hospital for the Paralyzed and Epileptic at Queen Square, in London. There are 188 illustrations, most of which were made at this hospital, from which also much of the clinical material utilized in the preparation of the book was drawn. We regret to note the absence of a bibliography, scarcely any references being made even to recent literature. Several disorders, usually described in works on the nervous system, *e.g.* myxedema, acromegaly, exophthalmic goiter, are omitted. The majority of subjects treated seem to be brought well up to date. In plan, the book is divided into nineteen parts. Part I is devoted to the anatomy and physiology of the motor, sensory, and cerebellar systems. Part II, to the examination of the nervous system in a case of nervous disease. Part III to the special senses. In succeeding chapters, on the cranial nerves, diseases of the brain, diseases of the spinal cord, etc., the descriptions are preceded in each case by a discussion of the anatomy and physiology appertaining to the particular subject in hand. This immediate juxtaposition, as it were, of structure, function, and disease or disorder adds to the practical nature of the work. While calling it a textbook, the authors do not claim for it completeness, and it is possible that in this respect the reader may be occasionally disappointed in the book.

Modern Medicine. Its Theory and Practice. In original Contributions by American and Foreign Authors. Edited by William Osler, M.D., Regius Professor of Medicine in Oxford University, England; formerly Professor of Medicine in Johns Hopkins University, Baltimore; in the University of Pennsylvania, Philadelphia, and in McGill University, Montreal. Assisted by Thomas McCrea, M.D., Associate Professor of Medicine and Clinical Therapeutics in Johns Hopkins University, Baltimore. Vol. VII, Diseases of the Nervous System, Mental Diseases, General Index. Philadelphia and New York: Lea & Febiger, 1910.

In this, the closing volume of Osler's system of medicine, the high standard of the previous volumes has been well maintained. The list of contributors comprises men who are all well known and many of them prominent, and the character of the articles they have prepared evidences the interest they have taken in the work. The opening chapter, by Lewellys F. Barker, is an introductory to diseases of the nervous system, in which the general phenomena attending nervous disorders are described and the methods of examination broadly sketched. William G. Spiller contributes a section on the diseases of the motor tracts, and Colin K. Russel discusses the combined system diseases of the cord, including pellagra. The following chapters on the scleroses of the brain and the diseases of the meninges are by Edwin Bramwell, who gives an excellent résumé of the value of lumbar puncture in the diagnosis of nervous diseases. E. Farquhar Buzzard takes up the diffuse and focal spinal diseases, and the important subject of the topical diagnosis of disease of the brain has been allotted to Joseph Collins, who also contributes the article on aphasia. Henry M. Thomas is the author of an admirable discussion of the diseases of the cerebral vessels, most of which, of course, is devoted to apoplexy. Two chapters of more than usual interest are those on tumors of the brain and meninges and on hydrocephalus, both by Harvey Cushing. The chapter on diseases of the peripheral nerves is by Gordon Holmes, and is a good one, though it must be admitted that the five lines devoted to the treatment of shingles by this author will probably disappoint the young practitioner who turns to this volume for help on encountering his first case of the disease. The article on the cranial nerves is by E. W. Taylor, and those on paralysis agitans, chorea and allied states are by Daniel J. McCarthy. Acute encephalitis and brain abscess have been given to E. E. Southard. A masterly chapter on epilepsy is contributed by William P. Spratling. Bernard Sachs writes on the important subjects of the syphilitic and parasyphilitic diseases of the nervous system, and also on amaurotic family idiocy. Charles W. Burr is the author of an excellent chapter on neurasthenia and the traumatic neuroses and psychoses. Two of the most interesting and valuable sections in the book are those on migraine, neuralgia and occupation neuroses, and on hysteria, by Smith Ely Jelliffe, the latter being an especially noteworthy contribution to the literature of the subject. With a work that is the product of so many different hands it is not possible in a brief notice to deal critically with the individual sections, and the reviewer must confine himself to generalizations. While it is true that some defects present themselves, such, for example, as a deficiency in anatomical illustrations, diagrams of functions, etc., and the scantiness of the bibliographical references furnished by many of the writers, on the whole the volume is eminently satisfactory. With the completion of the enormous task involved in the preparation of such a series of volumes, editors, contributors, and publishers deserve the gratitude of the profession for having made a contribution of the greatest value to medical literature and for having thus summed up, as it were, and placed on record the present state of knowledge in our profession. The work is truly worthy of its title, and no doubt will long stand as one of the most useful and practically valuable systems of medicine.

Studies in Immunization and Their Application to the Diagnosis and Treatment of Bacterial Infections. By Sir A. E. Wright, M.D., F.R.S.; Director of the Department for Therapeutic Immunization, St. Mary's Hospital, London, W.; late Professor of Pathology, Army Medical School, Netley. New York: William Wood & Company, 1910.

Now that the status of vaccine therapy as a remedial agency of the highest value has been definitely established, it has become a matter of the greatest importance that all the data so far available—both experimental and clinical—should be presented in concrete form, so that the practitioner may properly inform himself as to the utility and limitations of the method. It is, after all, for his benefit that the vast amount of research has been carried on, and he is the one who can most usefully employ any new weapon against disease that science has forged. It is therefore very desirable that the present volume should find a wide circle of readers, for in it Sir A. E. Wright traces the development of the subject from its earliest stages by the exceedingly instructive method of presenting in suitable order the relevant papers published by himself and his pupils. This plan of presentation, in which the reader is obliged to follow step by step the processes of the investigator's mind, is not only interesting, but also distinctly useful in that each new fact ascertained impresses itself with the greatest precision, and every link in the chain of reasoning becomes apparent. Part I contains papers on the bactericidal elements of the blood fluids, and these fall into three groups, dealing respectively with the agglutinins, the bactericidens, and the opsonins. In Part II the author has arranged in chronological order the papers dealing with therapeutic immunization proper, and these he groups into three periods. In the first the conception of vaccine therapy is developed from laboratory experiments into a method susceptible of practical application. In the second the difficulties and complicating factors that present themselves are considered and means for their control suggested. The three papers of the third series express the author's present views and summarize both the theoretical considerations and the practical questions involved. Of especial interest in this connection are the pages in which he considers the arguments of those who hold that regular determinations of the opsonic index are not necessary to success in vaccine therapy, and expresses the conviction that while there are cases with sufficiently pronounced external clinical manifestations to justify such a course, there are others in which it is absolutely essential to check the results of the treatment by systematic determinations of the index. The book is fascinating, both in subject matter and in style, and familiarity with its contents is a requisite to a proper understanding of this highly important development in the treatment of disease. The index is worthy of especial mention, for by means of its very ingenious and complete system of subheadings it forms what is practically a synopsis of the entire work and does much to overcome any element of discontinuity that the mode of presentation in separate papers entails.

Society Reports

BRITISH MEDICAL ASSOCIATION.

Seventy-eighth Annual Meeting, Held in London, July 26, 27, 28, and 29, 1910.

(Special Report for the MEDICAL RECORD.)

GENERAL MEETINGS.

Tuesday, July 26.

The presidential address was delivered in St. James Hall, Great Portland street, on the evening of July 26. There was a large assembly brilliant with the academical dresses of the various universities, foreign as well as English. On the platform members of the Council were accommodated and foreign guests and oversea delegates occupied the front of the area. Punctually at 8:30 P.M. The president, Mr. H. T. Butlin, P.R.C.S., D.C.L., LL.D., took the chair, all the audience standing up to greet him.

Presentation of the Presidential Badge.—Dr. FORD ANDERSON then presented him on behalf of the Metropolitan Counties Branch a presidential badge of gold, and some amusement was caused as he went to place it round the neck of the president, as the latter showed much uncertainty as to whether he should turn his back to him for the purpose or his face. A smaller gold replica was then presented to him, that he might retain it as a permanent memento of his year of office. The president then announced that H.M. the King-Emperor had graciously consented to become Patron of the Association. The assembly then rose to their feet and sang "God Save the King." The foreign guests and the delegates from the oversea dominions were then presented to the president. Among the former were Prof. Kocher of Bern, Dr. Lucas Championnière of Paris and Drs. L. Duncan Bulkley and Tait Mackenzie of the United States.

Mr. EDWARD OWEN in a felicitious speech introduced the Right Hon. Walter Long, M.P., who, together with the Right Hon. the Earl of Crewe, K.G. (unavoidably absent), had been elected an honorary member of the Association. He dilated on the great services of the Right Honorable gentleman in the prevention of disease, chiefly in the complete eradication of hydrophobia from these islands, a result which he attributed to his intelligence, his perseverance, in fact he might say his "doggedness." Finally he announced that in the interests of the Right Honorable gentleman's friends he had to inform him that the membership did not carry with it license to practice.

Mr. LONG was heartily received when he came forward to return thanks and spoke in high praise of the way in which his staff and the officials under him, mentioning especially Major Tennant, had by their loyalty, energy, and perseverance rendered possible the attainment of the goal of his work. The Stewart prize had been awarded to Major George Lamb, I.M.S., Director of the Pasteur Institute of India and Senior Member of the Plague Research Commission in India, in recognition not only of his own work, but also of the entire work of the Plague Research Commission and of every member thereof. The Major was unfortunately prevented by illness from coming personally to receive the award.

The President's Address.—Mr. HENRY T. BUTLIN, the president, then gave his address; he said that in the choice of a subject for his present address he was actuated by a knowledge that he had been chosen for that high post on account of his past services to the Association. In electing him to the office of president they had in effect said to him "Thou faithful servant, enter thou upon this office." He, therefore, desired to tell something of what the Association had accomplished for medical reform, especially for the benefit of the foreign delegates who might be less cognizant of it. They must not think that the annual meeting was a time of mere feasting and junketing, on the contrary, great, solid, and lasting work had been performed at these meetings. He would take them back to the annual meeting of 1871 at Plymouth, when Lord Lister was in the chair. Lord Lister was then a quiet, unassuming, little-known surgeon, and his address might have appeared tedious from the amount of detail contained in it, yet it was an historical address because in it Lister announced the great teachings on aseptic surgery which will always be associated with his name and concluded with the prophetic words "the sooner the profession come to recognize this the better it will be for humanity." Following this they had a remarkable meeting at Worcester when Sir William Stokes with the impassioned eloquence of the Irish race advocated the same principles. Then he would remind them of the meeting of 1904 at Oxford when the great Listerian principles were summed up in a remarkable address on surgery by a Scotchman, Sir William Macewen.

Thus the Association had been instrumental in bringing these great principles before the profession and hastening their adoption. He would remind them again of a remarkable address by Sir James Paget at Cambridge in 1880 when he spoke of the consequences of injury and disease to the structure of plants. Thus the meetings of all their twenty-one scientific sections were calculated to promote the progress of medical science and the benefit of humanity at large.

He then went on to speak of all that the Association had accomplished in the matter of medical reform, vaccination, registration of birth and deaths, medical treatment of paupers, suppression of quackery, and so forth. Eighty years ago the legal qualifications required to enable a man to practise medicine, surgery, and midwifery were very hazy and unsatisfactory, and through the influence of the Association a Royal Commission was appointed in 1834 to investigate. In 1842 a memorial was sent up to the Home Secretary, Sir James Graham, urging the necessity for a uniform minimum qualifying examination. The memorial was rejected and though again presented in the following year, it met with the same fate. In 1844, however, a bill for this object was brought into Parliament, but lost. In 1854 another medical bill was brought forward, but shared the fate of its predecessor. In 1856, the year in which the old Provincial Medical and Surgical Association adopted its present name of British Medical Association, another bill was brought into the Houses and supported by Lord Palmerston, but though the cause of medical reform was steadily advancing, it was only in 1858 that the Medical Act was passed and the General Medical Council was constituted. This body did not, however, give that satisfaction to the profession which had been hoped for from it chiefly from the want of direct representation of the medical profession thereon; when Sir Charles Hastings, the original promoter of the scheme, died no other medical representative was appointed in his place. In 1868 another attempt was made, though unsuccessfully, to gain direct representation in the council. In 1881 a royal commission was appointed, and in 1886 the Medical Act Amendment bill became law and it became necessary for everyone who desired to practise as a doctor to obtain a qualification in medicine, surgery, and midwifery, and the profession obtained direct representation in the General Medical Council. Mr. Butlin then went on to describe how the Association had encouraged original research. They did this firstly in 1874 by setting aside money for scientific grants to original investigators. One of the first investigations was on the subject of alcohol. In 1884 they went a step further and established two scholarships for research of £150 each. This departure was severely criticized at the time by certain members who would have preferred to have seen their money expended

on more directly utilitarian objects, such as the suppression of quackery or the defence of members, but he was reminded of the history of Faraday, which taught us that research, which seemed at the time to be purely scientific and far removed from practical application, turned out to be of the greatest practical importance to the profession and to humanity. Then they had expended £1,500 in the formation of committees for the investigation of chloroform anesthesia.

In 1883 the committee for the investigation of myxedema was instituted and this led to the grant of £50 to Sir Victor Horsley for his researches, which form the foundation of our modern thyroid therapy. A grant was also made to Surgeon Captain Bruce for the study of Malta fever, though this grant was returned as it was not required. They had thus been instrumental in equipping and advancing some of the most epoch making researches of the age. Then there was the Benevolent Society which had expended £76,000 in annuities, and an equal amount in grants to impoverished medical men and their families, and by the expenditure of £4,500 annually were doing much to relieve those who were in reduced circumstances through unavoidable misfortunes. Finally he appealed to the 22,000 members of the Association to stand by it and by one another and to look more and more to the British Medical Association for the realization of the objects of Medical Reform and Scientific Progress.

Sir William Whitla then proposed a vote of thanks, which was seconded by the Professor of Surgery at the Melbourne University, and carried by acclamation.

Address in Medicine.—Dr. J. Mitchell Bruce of London delivered this address, taking as his subject, "Recent Progress in Medical Science." In his opening remarks the speaker dwelt briefly on the advances made in medicine during the past few years, instancing, among other things, the discovery of the spirochete of syphilis; the rôle played by the mosquito in malaria and yellow fever and by the goat in the diffusion of Malta fever; the connection of a trypanosome with sleeping sickness, of the Leishman-Donovan body with kala-azar, and of the *Diplococcus intracellularis meningitidis* with cerebrospinal fever; the existence of typhoid carriers had been fully demonstrated. Investigation had been pushed forward into the relation of human to bovine tuberculosis and stringent regulations had been framed in respect of milk and meat as foods. The effects of oral sepsis had been worked out. We had improved methods of diagnosis in blood examination, special interest attaching to the Widal reaction in typhoid and the Wassermann reaction in syphilis. A read advance had been made in the introduction of lumbar puncture in cerebrospinal diseases. Among the new methods of treatment special place should be given to serum-therapy and vaccine-therapy. Of new drugs the most important were synthetic compounds with hypnotic and analgesic actions. In touching upon the inroads of surgery the claim was made that medicine had gained as much as she had lost by them, for while surgery had effected in treatment much that medicine failed to do or could never attempt, she had greatly increased our knowledge of diseases of the viscera, and not only of their diseases but of their disorders, and even of their condition and functions in health.

From this Dr. M. Bruce passed to the consideration of the greatest of the changes wrought in medicine by the discovery of phagocytosis, by virtue of which she steps forward from the study of lesions to the investigation of processes, of original causes, and of controlling circumstances. He reminded his hearers that with a few exceptions all the advances of the past 15 years had been in the field of etiology, and the doctrine of causation had been lifted to a dominant position in medicine, so much so that a methodical investigation was now made of the bacteriological relations of infective processes in the blood and tissues in every instance of acute febrile disease. With all that had been done in this field much still remained to be done. The usefulness of serum-therapy and vaccine-therapy was still far from settled. Diphtheria, typhoid fever, the pathological effects of the *Bacillus coli*, and certain skin diseases yielded to the method, and acute pneumonia sometimes, but the medical septicemias, tetanus, and even tuberculosis, after all the work with tuberculin, too often did not. The speaker then discussed at some length the influences concerned in the causation of disease, dividing them into three heads: (1) The cause which we called essential, the specific infection, an extrinsic influence; (2) the patient's resistance to the specific infection, an intrinsic element, and (3) the incidental or concomitant circumstances, which were of great variety both in kind and in their manner of action, and which were peculiarly the province of the medical practitioner, whose duty it was to know the circumstances and life-history of his patient, and to recognize that what we dignified with the name of natural resistance was but the product, after all, of all the influences that had befallen the man—racial, congenital, and personal. Reference was then made to the almost countless disorders of the different systems, especially the nervous system, outside of the acute infections, with which medicine must deal, and the question was considered as to how far it was possible to trace the common diseases to the common influences around us; and here the practitioner had the field in great measure to himself. He approached each case in the spirit of a naturalist, seeking the assistance of the pathologist when necessary. After citing many instances in which the naturalist method was now employed Dr. Mitchell Bruce concluded this section with the remark: "We are no longer satisfied with what may be called the 'anatomical' stage of diagnosis, but must press our inquiry deeper and do our best to discover in what the anatomical change originated. The minds of the profession will not rest until the cause of cancer has been found."

The speaker, in his summing up, would convince his hearers that though much had been done in the past, much more yet remained to be accomplished, and a great part of it was waiting to be done by the family practitioner. Conviction of the importance of etiology must carry with it a sense of duty. Everything could not be left to the bacteriologist. General practice was the most fruitful and promising field for the study of the natural history of disease in the living body.

This address was listened to by a very large and appreciative audience, and at its conclusion Dr. Mitchell Bruce received a vote of thanks from the association.

In the evening a reception was held at the Guildhall and was attended by large numbers.

Thursday, July 28.

The Temperance Breakfast.—The day began with a breakfast given to members of the Association by the National Temperance League. This has now become an annual institution and is looked forward to by advocates of the temperance movement and by a number of sympathizers with it. There is, of course, some speechifying on the subject, and the arguments for and against the consumption of alcohol by the healthy and its use in disease are set forth year by year at this breakfast.

Address in Surgery.—Dr. H. Gilbert Barling, Professor of Surgery in the University of Birmingham, delivered this address. After tendering his thanks for the honor implied in the invitation to address the meeting, Dr. Gilbert Barling announced that he had chosen "Malignant Disease" as his subject. He said that in spite of the new era in surgery founded on the genius of Pasteur and Lister, and the revelation of bacterial and allied infections as the cause of so many diseases, which had inspired the hope that the origin of cancer would be dis-

covered, the secret was still hidden. At the same time our knowledge of the processes of malignant disease, of the struggle made by the organism against it, and of the means by which we might relieve or cure was advancing in a most hopeful manner. The view held but a few years ago that cancer was a systemic disease, of which the tumor was the local manifestation, provided a disastrous example of the influence of bad theory on practice, as it led in most cases to a totally inadequate removal of the disease. We could appreciate our present advance only by reviewing our position from the three sides—experimental, pathological, and clinical. The speaker then divided his subject into the three main considerations—(1) What experiment has taught us as to the growth of transplanted carcinoma and the methods by which immunity can be conferred on inoculated animals; (2) our knowledge of resistance to malignant disease in the human subject; (3) the means available for its successful treatment.

Experimental investigation had taught us that carcinoma was a parasite, the essential element the epithelium, living its own life and using its host as a provider of nutrition through the new stroma and its accompanying blood-vessels. But we had learned also that, not content with exciting a production of new stroma and blood-vessels to supply its needs, the epithelial cell so impressed the tissues in which it was implanted that a stroma was produced exactly similar to the stroma in the primary growth. If the stroma of the primary tumor were highly vascular, so that the growth was of the hemorrhagic type, this would be exactly reproduced by successful inoculation. Experiments had been devised to determine whether what seemed to be natural resistance on the part of some mice could be increased, the results proving that this could be done, but only within narrow limits. We had also learned something by our study of the action of radium upon malignant tissue. If a portion of mouse carcinoma were exposed to the action of radium for a period insufficient to produce any structural change, gross or microscopic, and this fragment were subsequently inoculated into other mice, the inoculation failed, no growth taking place. In mouse carcinoma already established by inoculation, exposure to radium caused some of the tumors to disappear, others continued to develop normally, and a few perhaps flourished more actively. Study of these tumors would show as the most noticeable change an active proliferation of the connective tissues and an invasion of the parenchyma of the tumors by young fibrolasts which, as they completed their development, contracted on, strangled, and destroyed the epithelial cells they embraced. We had, however, no evidence here of a direct specific effect on the epithelium of the growth which was found to be still actively proliferating. Some experimental observations made by Mr. Percival Mills showed similar changes induced by exposing the liver of a healthy mouse to the action of radium. In his consideration of human resistance to malignant disease Mr. Barling said that we had evidence, both pathological and clinical, of a real struggle which occasionally ended in a spontaneous cure. In its progress through the lymphatic vessels, the latter become more and more distended until the walls ruptured; a slight hemorrhage might occur and some reaction of surrounding tissue. As a result fibrous tissue was produced, contraction followed, and the cancerous epithelium was strangled. Similar resistance might be found in the blood-vessels, as was most easily demonstrated in the lungs. Human resistance was also shown by late recurrence in patients who had been thought cured by operation perhaps ten years before, so that it was impossible to avoid the conclusion that minute foci might lie latent in the tissues for long periods. Spontaneous recovery was perhaps oftener cited than verified, yet rigid scrutiny would show not a few cases which appeared conclusive, among them notably the classic case of Pearce Gould, in which a woman with recurrent breast cancer, extensive gland infection, nodules in the skin, and growth in one femur with spontaneous fracture, who was reduced to death's door, was found four years later to have lost all sign of her disease, save a shortening of the femur from the spontaneous fracture.

In his consideration of treatment Mr. Barling dismissed treatment by serums, by drugs, and by the enzymes as futile. The *x*-rays had a real field of usefulness in relieving pain, and reducing the activity of inoperable growths. Of radium it was necessary to speak cautiously. Often it produced a profound impression; malignant tumors of great size might diminish or disappear. Unhappily their subsequent return was too often seen, and in some cases, instead of recession of the growth, there was a more rapid evolution. It was to be welcomed in inoperable cases for the lessening of pain and discharge and for the cicatrisation of open sores. In his consideration of Coley's toxin treatment Mr. Barling was not able to speak with much optimism, although he said that in cases that were inoperable, or where operation was refused, he would certainly advise the use of the toxins, with the expectation of benefit in a few cases. But we must still rely upon operative measures as the great remedy for malignant disease. The one real opportunity of cure was offered at the first operation, which should be pressed to its fullest extent. Our great hope for the future was in the direction of earlier recognition; in its earlier stages cancer was generally a silent disease, and physicians owed it to the public to urge special methods of investigation by instruments of precision, by radiography, by exploratory incision, or even by prophylactic excision. Mr. Barling concluded by expressing his belief that all malignant growths could be cured if they could be excised at a certain stage in their development.

In the evening some 350 ladies dined together on the invitation of the Ladies' Reception Committee. The Countess of Aberdeen and Mrs. Butlin received the guests.

Entertainments of various kinds and hospitality have been the order of the day—or rather of the week. So much so that few can be mentioned for they seem to have quite overshadowed the serious work. On Monday the president gave a dinner at the Hotel Cecil to 350 guests. On Wednesday he was in turn entertained at a luncheon by the staff and school of St. Bartholomew's Hospital, when there was much glorification that for a second time a Bart's man had been made president, and moreover, that Mr. Butlin was at the same time president of the Royal College of Surgeons. The Master and Warden of the Apothecaries gave a dinner in the evening, when, too, the Lord Mayor and Lady Mayoress and Corporation gave a conversazione in the Guildhall to about 1,500 guests, to whom the band of the Royal Artillery and that of the Coldstream Guards contributed the music for dancing which took place in the library.

To-day, Friday, some sections continue, but entertainments prevail, and to-morrow will be given up to excursions for the benefit of those who remain in town.

SECTION OF MEDICINE.

Wednesday, July 27—First Day.

Pathogenesis, Prophylaxis, and Treatment of Acidosis.—Professor D. L. EDSALL (Philadelphia) opened this discussion. It was known from experiment on animals that acid intoxication could occur and that the organism fought it by using ammonia in chief. In diabetes in human beings it was known that oxybutyric acid was the chief toxic element which was fought by ammonia and other bases. Diacetic acid and acetone were of little importance as toxic factors. Acid intoxication might not be the whole cause of the severe symptoms of diabetes, the kidneys were apt to be

damaged, giving an uremic factor and the acid itself gave rise to disorders of metabolism carried on in other organs. While there was an important distinction between acidosis and acid intoxication, there was from the clinical as well as from the pathological standpoint another equally important distinction between the forms of acidosis, sometimes severe and sometimes mild, that were due to lack of carbohydrates or inability to utilize them, as in diabetes, and those forms which were incidental to severe disease which was most commonly situated in the liver. Even in the latter forms, however, diet at times played an important part in treatment as to alkalies, probably less through checking the direct effects of acidosis than through controlling secondary effects, perhaps an autolysis. While therefore it was not certain that acid intoxication was the prime cause of the violent toxic symptoms in diabetes —and some evidence points to the contrary—it was highly probable that it was the main cause, as well as in the occasional cases of coma of the same type in nondiabetic persons. Starvation, post-anesthetic intoxication, acute yellow atrophy of the liver, vomiting of pregnancy, cyclical vomiting, eclampsia, and other conditions had probably a similar causation. It had been shown for example that anesthetics flooded the organism with fat. Changes in the liver were clearly demonstrable. Even a small quantity of acidosis might produce profound changes in the liver. The manner in which the acids produced their effect was probably a direct effect on the nervous system. The effect of the acidosis might be much of the same nature as the effect of a narcotic on the system possibly directed, especially to the lipoids of the nervous system, although part of the toxic effect was probably on the circulation. The relation of the loss of inorganic salts to the production of symptoms, and the possible relation of the same salts to the production of acidosis, needed further study. It was not improbable that these salts had some relation to the symptoms in the earlier course of diabetes before severe toxic symptoms came on, especially to the common muscular fatigue. Interdependence of carbohydrate metabolism and fat metabolism was alluded to, also to the equilibrium in the body of oxybutyric acid, diacetic acid and acetone. Alcohol had a marked influence in controlling acidosis and should be administered in generous quantities; glycerine aldehyde was another substance with a controlling effect, and it had not a toxic influence. The more a patient had the power of protecting himself in regard to carhobydrate the greater power he had against acid intoxication.

Dr. E. I. Spriggs thought the distinction that had been made between the different forms of acidosis was a superficial one, as also was that between cases in which there was obvious degeneration of the liver and in those in which there was not. It was doubtful if the acidosis itself had a direct effect on the autolysis of the liver—it was probably due to a separate poison. In diabetes it had been proved that the condition was one of acid poisoning and that the coma was mainly, if not entirely, due to it. Reference was made to the observations of Dr. Pembrey, Dr. Beddard, and himself on cases of diabetes. Acidosis might be produced by excess of carbohydrate or by starvation or a too rapid diminution of carbohydrate. Slight evidence of acidosis appeared in a few days after a diabetic diet was commenced which might develop into coma. To prevent acidosis the patient should have precisely the amount of carbohydrate that he could assimilate. A slight increase in carbohydrate in the diet might be followed by a fall in the oxybutyric acid. The other chief treatment was by sodium bicarbonate, which was only palliative.

Dr. Langdon Brown said that starvation was the chief cause of acidosis, particularly to the deprivation of carbohydrates. But acidosis might be due to oxygen starvation as in mountain sickness and in bronchopneumonia. It was not that oxybutyric acid was toxic so much as that they were evidence of severe destruction of the tissues. The alkalinity of the blood was not always diminished. In prophylaxis it might be found that the intolerance for certain carbohydrates was less than for other forms, *e. g.* cevulose might be well assimilated. Potassium citrate was a very valuable adjunct to the treatment by sodium bicarbonate. It was important that the tissues should not be flooded with sodium bicarbonate. The relative proportion of the salts that seemed necessary to maintain was in the ratio of 1 drachm of sodium bicarbonate, half a drachm of potassium citrate, and 3 grains each of carbonates of magnesia and lime.

Dr. A. P. Beddard also believed that acidosis was always due to carbohydrate starvation and that diabetes was the only condition in which acidosis was dangerous to life. In regard to the effect of exercise it was possible to give a diabetic too much exercise, but it was also possible to give him too little. Alkalies in diabetes might be used in diagnosis and treatment. It should be made out what dose of alkali was necessary to make the urine alkaline, the amount varying in different cases.

Dr. Leonard Guthrie referred to the question of post-anesthetic intoxication. It was not a question of overdosage or overconcentration, or idiosyncrasy. Starvation in this relation had, perhaps, been made too much of. He thought that all children the subject of cyclical vomiting were potential victims of postanesthetic intoxication.

Dr. M. S. Pembrey said that the acidosis was really a question of physiology in which the law of excitation came much into play. Sudden changes were more serious in their effect than gradual ones manifested in the effect of exercise or anesthetics on metabolism.

Dr. J. H. Ryffel alluded to the effect of severe exercise in producing acidosis and suggested that in this case the acid producing the acidosis was lactic acid.

Dr. Edsall, in reply, said the lack of success of the administration of alkali in many cases of acidosis was an argument used with force by those who held that the acid factor was not the only one in the intoxication known as acidosis.

Dr. Leonard Hill gave a demonstration on improved methods of giving oxygen with an account of the influence of air in treatment, arguing for the mere movement of the air in ventilation as distinguished from its change.

Section of Gynecology and Obstetrics.

Wednesday, July 27—First Day.

The president, Mrs. Mary A. D. Scharlieb, M.D., in her introductory remarks, welcomed the foreign visitors to the Section, Professors Gottschalk (Berlin), Doederlein (Munich), Nagel (Berlin).

Dysmenorrhea, Its Causes and Treatment.—Dr. G. E. Herman of London opened a discussion on this subject. He said that the first question to be answered was what was dysmenorrhea? Some said any pain or discomfort at the menstrual period, but this would involve a discussion of the whole field of diseases of women. His definition would be that the disease was one "sui generis" and that it was characterized by the occurrence of painful spasms of the uterine, the disease was frequently associated with deficient sexual feeling and sterility. It could be cured by dilatation of the cervix; he had come to the conclusion that about one-half of women menstruated without any pain or discomfort, and that about 1 in 8 were forced to lie up at the period. The pain was not relieved by lying down and did not last more than 24 hours, the patient often vomited and sometimes felt faint. The extreme severity of the pain was characteristic. Dr. Mackin-

tosh, in 1836, treated cases by dilatation of the cervix and had a large percentage of cures, but in those days before anesthetics and antiseptics, only the most severe cases would be submitted to this treatment. In his opinion the condition called obstructive dysmenorrhea did not exist, in complete obstruction leading to cryptomenorrhea there was little pain. In his opinion also the condition called membranoal dysmenorrhea did not exist, as robust women passed membrane without pain, and when there was pain with membrane it was due to weakness of the nervous system; when the latter condition was relieved the pain disappeared, although the passage of membrane might still continue. The size of the canal of the cervix had no bearing on dysmenorrhea. He would not include inflammatory dysmenorrhea in this discussion. The spasms of uterine colic were due to the absence of active dilatation of the cervix associated with uterine contractions. Nothing was known about the causes of dysmenorrhea, and it was impossible from a physical examination to predict the cases in which it would occur. Two-thirds of the cases began at puberty and one-third later, it very rarely began after 25. It occurred chiefly in women with highly developed nervous systems and showed no tendency to spontaneous cure; the only natural cure was pregnancy and this was usually effectual.

Discussing the treatment, the speakers said every patient could be cured by removing the ovaries and so arresting menstruation, but in many cases the cure would be worse than the disease. The pain could always be abolished by injecting morphia, but this was a dangerous proceeding. Coal tar analgesics were valuable and in his opinion were not productive of harm, in some cases they failed to relieve. Good food, rest, and sound sleep were all important. He had found most benefit from Guiacum resin given in 10-grain doses in cachet three times a day, beginning one week before the period; if this produced diarrhea he added 1 grain of pulvis ipecac co. (Dover's powder). The most effectual cure was dilatation of the cervix by mental bougies; he dilated up to No. 12, English catheter size, and preferred this scale to the millimenter graduation of Hegar's bougies. With regard to tents they sometimes remained constricted at the internal os and expanded above and below, and much difficulty might be experienced in their removal; if they were used he preferred two small ones to one large one. With regard to removal of the ovaries, if the patient had reached the age of 35 he thought science entitled to ask that this should be done, and, even at an earlier age, if a young woman was prevented from earning her living by the disease, he thought removal was quite justifiable.

Professor Gottschalk of Berlin said that narrowing of internal os and antiflexion might both be a cause; he treated cases by introducing laminaria tents, increasing in size on three successive days, and then packing with iodoform gauze for forty-eight hours. He spoke of mittelschmertz (middle pain) and said that it was caused by intermediate ovulation in severe cases, and by premenstrual engorgement of the graafian follicle in the slighter ones, and he treated it by scarification of the portio vaginalis.

Professor Magel of Berlin believed in membranous dysmenorrhea and in one case had removed the uterus for this condition after the remedies failed. He spoke of dysmenorrhea due to nasal conditions and he had seen some cases relieved by treatment applied to the nose.

Dr. Curtis Webb of London had seen great benefit from guiacum, also from abdominal compresses saturated in hot alcohol, as recommended by some French physicians. He found that the painful spasm could be relieved by static electricity and he had used an American static machine, passing one electrode into the rectum; he combined this with abdomen's dorsal application of the constant current of a strength of 60 milliamperes, or used the latter alone in single women. In the case of married women he used zinc-mercury ionization.

Dr. R. J. Johnstone of Belfast said that he would add to the definition Dr. Herman had given that the disease had no clear anatomical basis, and he compared the condition to the painful spasms met with in cases of anal fissure He believed that there must be some tearing of the fibres of the constricting muscle at the internal os if good was to be done, and, in some cases where dilatation had failed, he had seen good results from incision (Dudley's operation). In dysmenorrhea coming on some years after puberty he always found erosion present and treated these cases by excision of the erosion.

Dr. Inglis Parson of London divided cases into occasional and persistent; the former might be due to neuralgia, gout, or anœmia, the latter were always due to acute flexion; after dilatation he always left in a glass intrauterine stem for 14 days keeping patient in bed during this time.

Dr. Edge of Birmingham thought that many cases were due to girls being insufficiently fed between the ages of 9 and 17.

Dr. Blair Bell of Liverpool thought that atrophy of the uterine muscle and diseased endometerium lead to the formation of clots in the uterus and that these clots might cause an obstructive dysmenorrhea; he thought removal of the ovaries absolutely unjustifiable.

Dr. Murdock Cameron of Glasgow thought anteflexion a common cause and treated cases with silver intrauterine stem pessaries.

Dr. Frances Ivens of Liverpool thought that many cases were much relieved by purgation; he believed anteflexion was a cause.

The President thought some cases were due to obstruction of the cervical canal by pieces of membrane; he found good results from administering valeiranate of zinc and belladonna continuously for three or four months; he could not countenance removing healthy ovaries; he would prefer to remove uterus, leaving ovaries, if radical treatment was necessary.

Dr. Herman, in reply, said he would like to know what happened to the ovaries after removal of the uterus; he was under the impression that they would atrophy. Anteflexion was the natural position of the uterus and could not be a cause of dysmenorrhea. Grave dangers of septic infection were increased by using stem pessaries and there had been many fatal cases.

Bacteriology of the Genital Canal and the Prevention of Puerperal Fevers.—Professor Doederlein of Munich read this paper. He first discussed the question of preliminary disinfection of the genital canal in labor and said that he had made careful experiments in his wards at the same time; one part of the patients having the vagina washed and swabbed out with perthloride of mercury 1-1000, and in the others nothing of the kind was done, the genital canal not being touched; in all other respects the patients were treated exactly alike; in the first class the morbidity was 12 per cent., in the second 8 per cent., and he had come to the conclusion that preliminary disinfection of the vagina was contraindicated. He discussed the question of abdominal palpation, and while strongly advising its use he did not go so far as to prohibit internal examinations; as it had been proved that it was impossible to remove all microbes from the hands he advised rubber gloves for all internal examinations.

Dr. Ballantyne of Edinburgh drew attention to the difficulty of carrying out strict aseptic precautions in emergencies, such as severe postpartum hemorrhage, but urged that as much should be done as possible in this direction.

Dr. Herman thought gloves unnecessary, and apt to beget inattention to other means of disinfection; their cost was prohibitory for midwives.

Dr. Purslow of Birmingham used gloves for operative midwifery, but thought that it was difficult to separate an adherent placenta when wearing gloves.

Dr. Munro Kerr of Glasgow strongly advised gloves in all cases.

Dr. Kirkby Gomes of the Straits Settlements used gloves regularly in all obstetric work.

Dr. Blair Bell of Liverpool used sterilized cotton gloves for separating placenta and washable gloves for ordinary outdoor wear.

Dr. Edge of Birmingham drew attention to danger of introducing germs if the vulva was not carefully disinfected bfeore giving an intrauterine douche, when required in the puerperium.

Dr. Hastings Tweedy of the Rotunda Hospital, Dublin, filled the gloves with methylated spirit before putting them on and had tested the inner surface at the end of a two hours' operation and found it sterile; he agreed as to the difficulty of removing an adherent placenta when wearing rubber gloves.

Dr. Thomas Wilson of Birmingham strongly believed in gloves, but thought that they might be a passing phase and that some better method might take their place.

The President used glycerin instead of spirit to facilitate the putting on of gloves; in many cases of septic uterus he preferred the introduction of a glycerin pessary to washing out.

Air Embolism Due to Labor.—Dr. John Campbell of Belfast read a paper on this subject. He said that it was more common than was generally supposed. The symptoms in severe cases were like those of pulmonary embolism from clot, but in mild cases there were recurrent attacks of dyspnea. These attacks were due to contractions of the uterus forcing air into the blood stream. The cause of the entry of air into the uterus was delivery under anesthesia in the left lateral semi-prone position. In this position the expulsion of the child was followed by an inrush of air, but embolism was not produced until the placenta was detached. When this had happened the placenta might remain in the cervix, plugging it like a cork, and each contraction of the uterus would drive air into the sinuses. The prophylactic treatment was to complete delivery and carry out all obstetric operations with the patient in the dorsal position. When embolism had taken place the placenta should be immediately removed by hand and an intrauterine douche of saline solution given. In addition saline subcutaneous infusion, oxygen inhalations, and digitalis should be given. The patient should remain in bed five or six weeks.

Additional Cases of Rupture of the Uterus.—Dr. Munro Kerr of Glasgow read a paper with this title. As a result of his further experience he recommended that the cases should be treated by panhysterectomy followed by drainage of the lacerated broad ligament into the vagina, using a large rubber tube and gauge.

The Puncture of the Stroma in the Uterine Mucous Membrane and Its Bearing on the Menstrual Changes.—Dr. James Young of Edinburgh read this paper. He said that there were three theories of menstrual loss: (1) Transfusion from the blood vessels as a result of increased pressure in their interior, (2) Osmosis, (3) secretory activity of the epithelium, and he favored No. 2.

Section on Surgery.

Wednesday, July 27—First Day.

Sir Victor Horsley, President.

Operative Treatment of Simple Fractures.—Mr. Arbuthnot Lane said the subject under consideration was a very simple one. We had to determine whether the unoperative treatment of fractures was satisfactory in securing a useful limb or whether it was necessary to obtain acurrate apposition of the fragments by operative measures. Personally he was convinced that in the very large majority of cases of simple fracture of the long bones perfect result could be obtained by operative treatment alone. As regards the necessity of obtaining perfect apposition of fragmnts he was entirely in agreement and he could not urge the truth of this teaching too strongly. But as to the possibility of effecting such accurate apposition by the methods usually employed there was now no doubt whatever that the principle was not and never had been carried out in practice. In fractures of the shafts of the long bones where there existed any considerable displacement of the fragments, it was almost always impossible to restore the broken bone or bones to their original form by manipulation. If any one would still wish us to believe that he was able to obtain accurate apposition by such means let him produce *x*-ray photographs of his cases. That the inability to obtain accurate apposition of fragments was now fairly generally recognized was shown by the fact that the opponents of the operative treatment of fractures had changed their ground. They now asserted that the functional result did not depend on the perfection of the restoration of the form of the skeleton, but upon causes which they did not clearly define. These surgeons seemed to have a very vague idea of the mechanics of the skeleton. They experienced a great difficulty in arriving at a correct conclusion as to the amount of benefit their own patients derived from the treatment they themselves have employed. The speaker repeated a statement contained in a paper read before the Clinical Society in 1894 in which he urged on the profession the folly of continuing the old methods of treatment and the necessity of having recourse to operative procedures, namely, "That the treatment of fractures, as it exists, is a disgrace to surgical practice, because those who have sustained fractures, especially of the leg, only too often experience enormous physical disability. When dependent on labor for their income, they frequently suffer great finanial depreciation in their wage-earing capacity. In not a small proportion the depreciation in certain occupations amounts to 100 per cent." All his subsequent experience of fractures, treated by means other than operative, had fully borne out the accuracy of the conclusions he arrived at many years ago.

The advent of *x*-rays compelled surgeons to be more careful of their statements as to the necessity of effecting accurate apposition of fragments, and the temptation to cast discredit on the interpretation of *x*-rays became too great to be resisted by the surgeon. If these surgeons could have shown that the nature and amount of displacement of fragments were exaggerated by *x*-rays then the surgeons would have believed that they had succeeded in propping up a creed which was rapidly slipping away. Now as far as *x*-rays were concerned when taken by competent operators on up-to-date apparatus the results were in the speaker's experience perfectly intelligible and gave a thoroughly reliable indication of the displacement of the fragments. Far from exaggerating the difficulties of displacement they often underestimated them very greatly, since they did not afford any evidence of the soft parts which intervened between fragments and opposed their replacement. Mr. Lane would, therefore, assume that the *x*-ray photographs taken in planes crossing each other at right angles by an efficient *x*-ray expert with an up-to-date apparatus afforded sufficiently accurate evidence of the displacement for the purposes of the surgeon, and also that the same amount of information could not be obtained by any manipulation of the surgeon, however experienced and skillful.

The advantages gained by operative interference were that the broken bone was restored to its original form and

was capable of performing its normal functions. There was no doubt whatever that if the operation could be performed easily and safely by an average surgeon the operative treatment of fractures would have become popular long ago. The difficulties that beset the operative treatment of fractures were that to insure success an asepsis which was much more perfect than sufficed for other operations was requisite when a foreign body was left in a wound, as it was in the operative treatment of fractures, and the degree of asepsis requisite varied directly with the bulk of the foreign body. Also it was not possible to insure this degree of asepsis and to perform the large majority of these operations with the appliances in ordinary use and instruments specially adapted for the purpose must be employed. Otherwise we would not hear so much about plates and screws coming out of wounds, of the development of rarefying osteitis about screws, etc. If infection of the wound took place the result might be disastrous to the patient. Many of the operations were difficult to perform, especially when there were much comminution of bone and swelling of the surrounding soft parts, and, unless very great care was taken, a failure to secure perfect asepsis might arise during the course of a prolonged and complicated procedure. Until this was generally recognized by surgeons much harm would result from the general use of the operative treatment of fractures, but with an improved technique and an increasing familiarity with the operative procedure the danger of asepsis would cease to exist.

As to the best method of retaining the fragments of broken bones immovably in position the buried steel plate is in Mr. Lane's opinion the most effective and simple of application. A plate was readily secured to the fragments by screws, which in the adult engaged the proximal compact tissue alone. These were threaded along their entire length. If properly introduced they produced no irritation in an aseptic wound. The skin of the patient should be carefully excluded from wound area by means of sterile cloths fixed to the margin of the incision. The incision should be of ample length so as to avoid damage to important structures and to minimize any risk of infection. The instruments used for bringing the fragments into position for the introduction of the plates and screws for controlling hemmorrhage, etc., should be very long and powerful. No ligatures were required and no portion of the instrument, sponges, etc., which had touched even the gloved hand should come into contact with the wound. An epiphysis which was separated rarely required to be retained in position by a plate or screws, but should it be necessary to employ such means the plate should be removed as soon as union had taken place to avoid any interference with the growth of bone at the epiphyseal line. In fractures of the ends of long bones it was also rarely requisite to retain the fragments by means of a plate, once accurate apposition had been effected, provided the joint were fixed in a suitable position. One must always remember that whatever means were used it was absolutely requisite to immobilize the fragments, and to adapt the plates accurately. There were of course limits to this operation, especially in cases where the bones were so soft that the screws could not hold; but in regard to this the speaker was convinced that alcohol had a worse influence on bones than on any other tissue of the body. Finally Mr. Lane emphatically asserted that it was often impossible to replace fragments satisfactorily by manipulation, and any compromise was unjustifiable.

Dr. Lucas-Championnière of Paris admitted that Mr. Lane had given a good demonstration of the possibilities of operative treatment in cases of simple fracture. Possibly others could not have given such good results. For himself, he was satisfied with other methods of treatment in most cases. Perhaps in very bad cases of fractures of the lower part of the leg Mr. Lane's method would be especially useful. Accurate position of the bones was not the only consideration, and he had seen many cases of good results so far as usefulness of the limb, with bad apposition of the fragments. With his own methods he usually obtained good results after 14 days' massage. In two cases in which he had sutured the olecranon, the result was bad from immobilisation. In conclusion, he was satisfied with a simple operation, and he thought the major operation should only be undertaken by an expert who would not kill his patient. You had no right to kill a patient with a simple fracture, although Mr. Lane might expect some of his patients to die. They were so nearly dead to begin with.

Mr. Gilbert Barling of Birmingham said it was difficult to reconcile the two views on this subject. He suggested that possibly the time had now arrived for the British Medical Association to appoint a committee to determine the truth of this matter. Or, were we to go into two camps? The profession wanted some guidance. There was some excuse for conservatism, for, as the last speaker had said, a living dog was better than a dead lion. Operative measures unquestionably implied danger to life in some cases, and suppuration with necrosis and delayed recovery in others. Much depended on the technique. He had seen Mr. Lane operate, and he knew that his technique was perfect. For his own part, as methods of surgical asepsis improved, he felt able to undertake operative cases which ten years ago he would have hesitated to touch. He would plead for a careful selection of cases, and also for a careful selection of operator. In the light of radiography many of the conclusions we arrived at without its aid were now proved to be inaccurate—especially in the case of fractures involving joints. And with the more frequent check to our diagnosis, we should probably be called upon to operate more frequently. It must not be forgotten that *x*-rays were not infallible, and we should often have to decide whether to be guided by *x*-rays, or by the question: "Is the patient likely to get a useful limb?" In all those cases in which we had to depart from our conservative methods, particularly in the case of oblique fractures and those of the olecranon, the method devised by Mr. Lane was unquestionably the best.

Mr. Deansley of Wolverhampton said that he had some correspondence with Mr. Lane on this subject 10 years ago, and although at that time he did not see eye to eye with him, he had now quite changed his own views. He still held, however, that in certain fractures perfect restoration of function may be obtained, even although the fragments are not in good position. It was not fair to compare the results obtained by Mr. Lane with those which house surgeons and comparatively inexperienced practitioners obtained from older methods. He thought that a skilled surgeon might often obtain good results by conservative methods, but even then, he believed that many cases might be operated on with advantage. We ought not to lay down any law, but the decision in each case should rest with the individual surgeon. And a man should not operate unless he felt certain of being able to exclude sepsis, and was willing to take the great responsibility which operation involved.

Professor Ch. Willems of Belgium thought we should be better employed in making ourselves perfect in the many bloodless methods of treating fractures, rather than in devising variety in open methods. He considered operations were justifiable only in rare cases. In those cases which were irreducible owing to the interposition of soft parts between the fragments, he made an incision for the purpose of reduction, but condemned any attempt at operative fixation. He preferred to fix the parts by plaster bandages applied above and below the wound. He did not maintain that his method gave such absolute accuracy of

opposition, but it ensured an excellent functional result. He considered his method more simple and less dangerous.

Mr. Walter Spencer of London was opposed to Mr. Lane's method in Pott's fracture and in fractures of the shafts of the femur. In the cases of Pott's fracture shown by Mr. Lane, the foot was still extended. He did not consider mechanical fixation was necessary, even in compound fractures of the leg.

Mr. Whitelock of Oxford considered the technique was difficult. He did not agree that you never get rarefying osteitis. In many cases the screws come loose, and may require removal. Even Mr. Lane admitted that he removed his early when near a joint—which was a concession. He (Mr. Whitelock) frequently used some absorbent suture, especially for the patella and near an epiphysis. If wire was used, a good result may apparently be obtained, and then in 6 or 12 months the patent may return with the wire loose. The justification for operation was not to get perfect alignment, but to remove any intervening soft tissue. If these are removed, good results may be obtained, even without suturing.

Mr. Paterson of London thought the trend of the discussion must be satisfactory to Mr. Lane. In former days he had been the subject of a good deal of hostile criticism, but we all ought to recognize the brilliant pioneer work he had done in the operative treatment of fractures. Hitherto too much attention had been paid to *immediate* results, and too little to remote ones. In addition to a good functional result, it was now-a-days necessary to get a good anatomical result as well to satisfy the law courts. The ordinary methods of treatment are not satisfactory, and the risk of operation is nil if properly performed in the way done by Mr. Lane.

Mr. Morton and Mr. Shenton gave some illustrations of skiagrams descriptive of cases of fracture treated by the two methods.

Mr. Hey Groves was surprised Mr. Lane had not shown any plates of fractures of the lower jaw, as he considered such cases very suitable for treatment by Mr. Lane's method. He considered that many cases of fractures of long bones might be treated more easily by inserting bone pegs into the medullary cavity of each fragment. He also advocated direct transfixion of bones as a means of using forced extension.

Mr. Fullerton thought many surgeons did not take sufficient interest in cases of fracture. He was not satisfied with the older methods, especially as used in many cases, and in the worst cases the only method was to mechanically fix as advised by Mr. Lane. Unfortunately, other operators do not share the same immunity from disaster.

Mr. Heygate Vernon contended that operative measures were imperative in all cases in which the displacement could not be reduced by manipulation.

Mr. Huggins said there was no record of any trouble with the plates or screws in any of the cases treated by operation at the East Ormond St. Children's Hospital.

Mr. Lane in reply said that hitherto whenever he had spoken on this subject, he had met with no support. Today, all his opponents had vanished and he met with practically unanimous support.

(*To be continued.*)

Pathological Society of Philadelphia.

At a stated meeting, held May 26, Dr. B. S. Veeder exhibited a specimen of "Duodenal Ulcer in an Infant Six Months Old." The child had presented signs of gastro-intestinal disorder, with malnutrition and blood in the stools. The condition is considered by some observers a relatively common one and operation has been successfully performed. Dr. Nate Ginsburg presented "A Left Kidney with Two Ureters." Each ureter arose from a separate pelvis of the kidney, while they entered the bladder by a common orifice. Dr. Ginsburg exhibited also "A Calculous Cast of the Renal Pelvis and Calyces." The kidney was cystic and the calculus entirely filled the pelvis and calyces. In addition the gall-bladder contained a calculus. Both specimens came from the dissecting room. Dr. B. A. Thomas exhibited a specimen of "Acute Suppurative Hematogenous Nephritis Caused by the Bacillus of Friedlander." Although a considerable portion of the kidney appeared to be diseased, urine stained with indigo-carmine was seen on cystoscopic examination to enter the bladder through both ureters after a short interval. The affection is often due to the *Bacillus coli communis*. Dr. Thomas exhibited also a specimen of "Acute Hemorrhagic Nephritis," the kidney being removed on account of repeated unilateral renal hematuria, and exhibiting well-marked histological changes. He exhibited also a kidney from a case of "Essential Nematuria." The organ was removed for the control of hemorrhage, but histological examination failed to disclose alterations in the texture of the kidney sufficient to explain the condition. The patient had had an attack of scarlet fever in early life. Dr. C. M. Montgomery presented a communication entitled "The Relation of Intestinal Absorption to Pulmonary Anthracosis," reciting the results of experimental observations undertaken for the purpose of determining whether insoluble materials introduced into the digestive tract found their way to the lungs and the bronchial glands or not. For this purpose an insoluble form of Prussian blue was employed, and after being mixed with batter and baked, it was introduced, in the form of cakes, or it was ingested in a dry state. Under the former conditions the powder found its way into the wall of the bowel and into the mesenteric lymphatic glands, but never to the lungs and the bronchial glands, while under the latter condition the lungs and the bronchial glands were affected. In other words when the possibility of inhalation was excluded lungs and bronchial glands escaped. Dr. H. T. Karsner presented a communication entitled "Primary Carcinoma of the Liver," in which he detailed the results of a clinical and anatomical study of nine cases, five of which belonged to the class of adenocarcinoma and four to that of solid carcinoma. The former apparently originated from the biliary apparatus, the latter from the parenchyma of the liver. In all of the cases there was some degree of cirrhosis. Pain was a relatively uncommon clinical phenomenon.

Drs. A. J. Smith and F. D. Weidman presented a communication entitled "An Amebiform Parasitic Infection Found in a Stillborn Child." Delivery was somewhat belated and the fetus had been dead but a short time. On examination of the body of the fetus amebiform bodies were found in liver, kidneys, and lungs. No source of infection could be determined.

Should the Cesarean Section Be Performed for Hemorrhage Due to Vicious Insertion of the Placenta?—J. Mouchotte gives the result of a study of 183 cases of placenta previa treated by the method of Pinard at the Baudelocque Hospital. This method is absolute inaction as long as there is no rise of the pulse beyond 100; when this rise occurs rupture of the membranes and the introduction of a Champetier de Rives balloon to act as dilator and tampon at the same time. Out of these 183 cases all but four survived, and 101 infants left the hospital alive. Of the 83 children which died, many were either not viable, or were so reduced by the loss of blood of the mother that when they came to the clinic, it was not possible to save their lives. Hence, none of them were worth doing a cesarean section with a view of preserving a living child. Of the mothers who died, one was infected before entry; another died of infection from handling in introducing three different balloons because of bursting of the rubber; another was exsanguinated when she reached the hospital; the fourth died of delay in introducing the balloons. Of the children who might have lived, twelve in number, only five were well developed when the mothers entered the hospital.—*Annales de Gynécologie et d'Obstetriques.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

UNIVERSITY OF THE STATE OF NEW YORK.

May, 1910.

ANATOMY.

(*Answer ten questions only.*)

1. What structures pass through the foramen magnum of the occipital bone?
2. Describe the patella.
3. Distinguish synarthrosis and diarthrosis. Illustrate each.
4. Give the origin, insertion, action, and nerve supply of *one* of the following muscles: Deltoideus, psoas major (psoas magnus), sternocleidomastoideus.
5. Mention the openings and the valves of the left ventricle of the heart.
6. Give the origin, course, and distribution of the arteria pulmonalis.
7. Describe the venæ intercostales.
8. Locate and describe the lymph nodes of the head.
9. Give the origin, course, and distribution of the nervus ischiadicus (great sciatic nerve).
10. Describe the nasal fossæ.
11. Give the structure of the stomach. What is the average size of the adult stomach.
12. Give the gross anatomy of the tongue.
13. Describe the pelvis of the kidney.
14. Describe the urogenital triangle (urethral perineum).
15. Give position and the shape of the pancreas.

PHYSIOLOGY.

(*Answer ten questions only.*)

1. What are the general functions of epithelium? What are the specific functions of ciliated epithelium?
2. Explain the dangers of transfusing blood from lower animals into man.
3. What are the forces that cause the circulation of the lymph?
4. Describe the mechanical relation of the ribs to the vertebræ. Explain the relation of this arrangement to respiration.
5. Give *three* examples of enzymes and state the specific functions of each.
6. Describe the plicæ circulares (valvulæ conniventes). Where are they found, and in what numbers? What purpose do they serve?
7. Mention in order of importance the avenues through which the heat of the body is lost.
8. Describe the glycogenic function of muscle.
9. What is the origin of urea?
10. Is a muscle dependent on its nerve connection for the reception of a stimulus? Explain.
11. Describe the effects of paralysis of the nervus facialis.
12. Describe the tuba auditiva (Eustachii), and state its function.
13. Illustrate by diagram or otherwise the formation of the image of an object on the retina, considering the refractive surfaces of the eye as a biconvex lens.
14. State the physical changes in the human body that are characteristic of senility.
15. What is the significance of the presence of polynuclear leucocytes in the blood?

CHEMISTRY.

(*Answer ten questions only.*)

1. Give the graphic formula of (*a*) sulphur trioxide, (*b*) phosphoric acid.
2. Give the meaning and illustrate the use in chemical nomenclature of (*a*) id, (*b*) ous, (*c*) ic, (*d*) hypo, (*e*) per.
3. State the centigrade and the Fahrenheit registration of (*a*) the boiling point of water, (*b*) the freezing point of water, (*c*) the freezing point of mercury.
4. Define and illustrate (*a*) distillation, (*b*) pentad element, (*c*) molecular weight, (*d*) gas, (*e*) acid salt.
5. Describe H_2O_2 as to (*a*) preparation, (*b*) uses, (*c*) test by which it may be recognized.
6. Give the occurrence, preparation, properties, and uses of NH_3.
7. What are the chief sources of iodine? Describe a method of preparing iodine. Give the formulas of *five* compounds of iodine.
8. Give the preparation, properties, and uses of sulphuric acid.
9. Give the chemical name, the properties, and the chief sources of K_2CO_3.
10. What is the chemical antidote for poisoning by lead?
11. Give an emergency method of preparing ferric hydroxide for use in a case of arsenic poisoning.
12. Mention the sources of glucose. Give a test for glucose.
13. Describe normal urine as to (*a*) specific gravity, (*b*) reaction, (*c*) color, (*d*) constituents, (*e*) quantity voided in twenty-four hours.
14. Give the formulas of *three* substances commonly employed as disinfectants. State in detail an approved method of using *one* of these substances as a disinfectant in a private house after an infectious disease.
15. Give the relative proportion of water found in (*a*) gastric juice, (*b*) human milk, (*c*) blood, (*d*) urine.

DIAGNOSIS.

(*Answer ten questions only.*)

1. Differentiate cerebrospinal fever and typhus fever.
2. Give the clinical history of a case of bubonic plague.
3. Describe the typical course of scarlatina.
4. Give the symptoms of pernicious anemia.
5. State the diagnostic value of blood count.
6. Give the symptoms of (*a*) cardiac hypertrophy with dilatation, (*b*) cardiac hypertrophy without dilatation.
7. What are the characteristics of acute endocarditis?
8. Give the symptoms and the physical signs of chronic bronchitis.
9. Make a diagnosis, by exclusion, of retropharyngeal abscess.
10. What are the symptoms of carcinoma of the stomach?
11. Give the clinical history of a case of invagination of the bowels.
12. Give the signs and the symptoms of acute hepatitis.
13. What are the symptoms of pyuria? Give laboratory methods of confirming the diagnosis.
14. Give the symptoms of chorea.
15. Describe an ambulance case of alcoholism, and show how the possibility of its being a case of cerebral hemorrhage has been eliminated.

PATHOLOGY.

(*Answer six questions only.*)

1. Describe the changes in the dura mater in pachymeningitis.
2. Describe a teratoma (dermoid cyst).
3. Describe the tissue changes in syphilitic ulcer.
4. Differentiate the blood pictures in lymphatic leukemia, Hodgkin's disease (lymphadenoma) and trichinosis.
5. Describe *three* varieties of thrombus.
6. Describe the tissue changes in an apoplectic area.
7. Describe the appearance of a section of the spinal cord in progressive spinal muscular atrophy.
8. Describe the tissues of the uterus in acute metritis.
9. What is metastasis? What are the most frequent channels of metastasis?

BACTERIOLOGY.

(*Answer four questions only.*)

10. Describe and illustrate a spirillum.
11. Describe the streptococcus, and mention *two* lesions caused by streptococcus infection.
12. Mention and describe the microorganism of influenza.
13. Describe the bacillus diphtheriæ. Mention *two* organisms that are frequently found with the bacillus diphtheriæ in cultures from the throat.
14. Mention and describe the organism that usually causes lobar pneumonitis, and state how its presence can be demonstrated.
15. Give *four* sources of infection, and state the comparative importance of each.

SURGERY.

(*Answer ten questions only.*)

1. Describe *two* methods of producing local anesthesia, and mention indications for the employment of each.
2. Describe aseptic wound fever (post-operation rise), and give the theory of its cause.
3. Give the symptoms and the surgical treatment of ischiorectal abscess.
4. What complications should be feared in a wound made by the wad of a toy pistol, and how should such a wound be treated?
5. Define lipoma. Describe the surgical treatment of a single subcutaneous lipoma.
6. Describe an amputation at the ankle joint.

7. What are the indications for osteotomy? Describe in detail osteotomy for deformed tibia.
8. Give the symptoms of subcoracoid dislocation, and describe a method of reduction by manipulation.
9. Describe in detail the operation of lumbar puncture.
10. Give the symptoms of ulcer of the stomach, and describe the surgical treatment.
11. Make a differential diagnosis of aneurysm and growth over a vessel.
12. Describe the surgical treatment of genu valgum.
13. Describe in detail the diagnostic points of prostatic hypertrophy.
14. Give the symptoms and the management of trachoma.
15. What measures should be taken to check primary hemorrhage following removal of the faucial tonsil?

OBSTETRICS AND GYNECOLOGY.

(*Answer ten questions only.*)

1. Define the terms abortion, miscarriage, and premature labor as employed in a strictly scientific sense.
2. What changes take place in the uterus after impregnation?
3. Give general directions for the management of a normal pregnancy.
4. What care should the breasts receive (*a*) during pregnancy, (*b*) during the puerperium?
5. Give the signs and the symptoms of pregnancy before and after quickening.
6. Describe the several stages of a high forceps delivery.
7. Mention *three* causes of dystocia and give the management of each.
8. Give a clinical description of puerperal insanity. State the causes and give the management of puerperal insanity.
9. Give an exact description of Credé's method of delivering the placenta.
10. What conditions indicate version, and how should it be performed?
11. Describe the secondary operation for laceration of the perineum.
12. Give the causes, symptoms, and management of puerperal eclampsia.
13. Describe the clinical management of a head-last labor.
14. Make a differential diagnosis of vaginitis and vaginismus. Give the treatment of each.
15. Give the causes, pathology, symptoms, and diagnosis of chronic endometritis.

HYGIENE AND SANITATION.

(*Answer ten questions only.*)

1. What are the functions of vegetable acids?
2. What precautions should be used in the collection and storage of rain water for drinking?
3. What general rules should be observed in bathing? Mention the benefits of cold baths. What physical conditions render cold baths inadvisable?
4. What should be the relative arrangement of desks and windows in schoolrooms? What injurious effects may result if this arrangement is not observed?
5. Describe *two* processes of freeing water from bacteria.
6. Describe the principles of construction of a self-cleaning sewer.
7. Why is unripe fruit unwholesome? Wherein are fruits valuable as food?
8. What general characteristics of an outbreak of disease would lead to the suspicion that the milk supply had become contaminated?
9. What is koumiss? What is kefir? How are these products made?
10. Illustrate the theory of immunity by means of antitoxins.
11. What agents are used for disinfecting ships and their cargoes? Describe the procedure.
12. Mention the principal means of preventing the spread of contagious diseases in schools.
13. Mention *six* diseases that may be acquired by eating the flesh of diseased cattle.
14. What relation has soil to malaria and to yellow fever?
15. What food principles predominate in (*a*) beef, (*b*) wheat, (*c*) eggs?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

UNIVERSITY OF THE STATE OF NEW YORK.

February, 1910.

ANATOMY.

1. *Structures that pass through the foramen magnum:* The medulla and its membranes, vertebral arteries, spinal accessory nerves, anterior and posterior spinal arteries, and the occipitoaxial ligament.

2. See Cunningham's "Anatomy" (1909), page 229; or Gray's "Anatomy" (1908), page 233.

3. *Synarthrosis* is an immovable joint; as in junction between cranial and facial bones (except lower jaw). *Diarthrosis* is a freely movable joint; as elbow, hip, knee.

4. DELTOID. *Origin:* From the outer third of anterior border and upper surface of the clavicle, from the outer margin and upper surface of the acromion process, and from the lower edge of the spine of the scapula. *Insertion:* Into the deltoid impression on the middle of the outer side of the shaft of the humerus. *Action:* It raises the arm from the side so as to bring it at right angles with the body; its anterior fibers draw the arm forward; its posterior fibers draw the arm backward. *Nerve supply:* The circumflex.

PSOAS MAGNUS. *Origin:* Transverse processes of lumbar vertebræ; also from bodies of last thoracic and all lumbar vertebræ, with the intervertebral substance. *Insertion:* Lesser trochanter of femur. *Nerve supply:* Second and third lumbar.

STERNOCLEIDOMASTOID. *Origin:* Upper and anterior part of manubrium, and inner third of upper border and anterior surface of clavicle. *Insertion: Mastoid* process of temporal bone and outer half of superior curved line of occipital bone. *Action:* Draws head to same side, or rotates face to opposite side; if both muscles act together, the head is flexed upon the neck. *Nerve supply:* Spinal accessory.

5. *Openings of left ventricle:* Aortic and auriculoventricular; *valves:* mitral and semilunar.

6. See Cunningham's "Anatomy" (1909), page 795; or Gray's "Anatomy" (1908), page 589.

7. See Cunningham's "Anatomy" (1909), page 873; or Gray's "Anatomy" (1908), page 752.

8. See Cunningham's "Anatomy" (1909), page 909; or Gray's "Anatomy" (1908), page 783.

9. See Cunningham's "Anatomy" (1909), page 648; or Gray's "Anatomy" (1908), page 1030.

10. The *nasal fossæ* are two large, irregular shaped cavities, situated one on each side of the middle line of the face, extending from the base of the skull to the roof of the mouth, and separated from each other by a median septum. They open in front by the anterior nares, with the face; and behind, by the posterior nares, with the nasopharynx. They are wider below than above. *Bones entering into their formation* are: Frontal, sphenoid, ethmoid, lacrymal, nasal, palate, superior maxillary, vomer, and inferior turbinated.

11. See Cunningham's "Anatomy" (1909), pages 1058 and 1053; or Gray's "Anatomy" (1908), pages 1281 and 1279.

12. See Cunningham's "Anatomy" (1909), page 1009; or Gray's "Anatomy" (1908), page 1007.

13. See Cunningham's "Anatomy" (1909), page 1141; or Gray's "Anatomy" (1908), page 1424.

14. See Cunningham's "Anatomy" (1909), page 1277; or Gray's "Anatomy" (1908), page 1549.

15. PANCREAS. *Position:* Transversely across posterior abdominal wall, behind the peritoneum, from the duodenum on the right to the spleen on the left; in the epigastric and left hypochondriac regions. *Shape:* Long and irregular prismatic; its shape has been compared to that of a human or dog's tongue.

PHYSIOLOGY.

1. *General functions of epithelium:* (1) Protection; (2) secretion; (3) motion (ciliary); (4) special sensation; (5) absorption. *Special functions of ciliated epithelium:* To keep foreign particles out of the respiratory tract, to assist the ovum in the Fallopian tube onwards to the uterus, to enable the spermatozoa to progress; generally—protection and motion.

2. *Dangers of transfusing blood from lower animals to man:* "The serum of certain animals possesses the property of dissolving the red corpuscles of another species of animals. The serum of a dog destroys the red corpuscles of a man; the hemoglobin is dissolved out. The serum, besides its action on the red corpuscles, is also active against the white corpuscles of the same animal, stopping their ameboid movements. The globulicidal action of the serum is related to its poisonous action on microbes. The normal serum of certain animals kills microbes, as the serum of the dog kills the typhoid bacilli. The power to kill red corpuscles and microbes is due to the presence in the serum of a substance, an alexin. In transfusion this plays an important part."—(Ott's *Physiology.*)

3. The forces concerned in the circulation of the lymph

are: (1) The presence of the blood in the blood-vessels; (2) thoracic aspiration; (3) muscular contractions of the voluntary muscles; (4) contractions of the intestine; (5) the action of the valves in the lacteals and lymphatics.

4. See Cunningham's "Anatomy" (1909), pages 269 and 272; or Gray's "Anatomy" (1908), page 285.

5. *Three enzymes:* (1) Ptyalin (of the saliva), which changes starches into dextrin and maltose.

(2) Trypsin (of the pancreatic juice), which changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin.

(3) Amylopsin (of the pancreatic juice), which converts starches into maltose. All of these act in an alkaline medium only.

6. See Cunningham's "Anatomy" (1909), page 1062; or Gray's "Anatomy" page 1299.

According to Sappey, there are about six hundred of these valvulæ conniventes in the upper half of the small intestine, and about two hundred to two hundred and fifty in the lower half.

7. Avenues through which heat of body is lost, in order of importance: (1) Skin, by radiation and conduction; (2) skin, by evaporation of the perspiration; (3) expired air; (4) excretions: urine and feces.

8. *The glycogenic function of muscle:* "It has been estimated that the percentage of glycogen in resting muscles varies from 0.5 to 0.9 per cent., and that in the musculature of the whole body there may be contained an amount of glycogen equal to that in the liver itself. Apparently muscular tissue, as well as liver tissue, has a glycogenetic function—that is, it is capable of laying up a supply of glycogen from the sugar brought to it by the blood. The glycogenetic function of muscles has been demonstrated directly by Kulz, who has shown that an isolated muscle irrigated with an artificial supply of blood to which dextrose is added is capable of changing the dextrose to glycogen, as shown by the increase of the latter substance in the muscle after irrigation. Muscle glycogen is to be looked upon as a temporary and local reserve supply of material; so that, while we have in the liver a general depot for the temporary storage of glycogen for the use of the body at large, the muscular tissue, which, considering its bulk, is the most active tissue of the body from the standpoint of energy production, is also capable of laying up in the form of glycogen any excess of sugar brought to it. . . . It is found that the supply of glycogen is greatly affected by conditions calling for increased metabolism in the body. Muscular exercise quickly exhausts the supply of muscle and liver glycogen, provided it is not renewed by new food. In a starving animal glycogen finally disappears, except perhaps in traces, but this disappearance occurs much sooner if the animal is made to use its muscles at the same time."—(From Howell's *Physiology.*)

9. Urea is principally formed in the liver; it is the end product of the metabolism of the proteids, being the result of the conversion, by the liver, of amino-acids absorbed from the intestines into the liver.

10. Ordinarily muscle is dependent upon its nerve connection for the reception of a stimulus; but muscle *can be* stimulated without any regard to nerve supply. Thus exposure of muscle to dilute ammonia (which has no effect on the nerve to the muscle) will cause contraction.

11. "When the facial nerve is paralyzed, the muscles of the face being all powerless, the countenance acquires on the paralyzed side a characteristic, vacant look, from the absence of all expression; the angle of the mouth is lower, and the paralyzed half of the mouth looks longer than that on the other side; the eye has an unmeaning stare, owing to the paralysis of the orbicularis palpebrarum. All these peculiarities increase the longer the paralysis lasts, and their appearance is exaggerated when at any time the muscles of the opposite side of the face are made active in any expression, or in any of their ordinary functions. In an attempt to blow or whistle, one side of the mouth and cheeks acts properly, but the other side is motionless, or flaps loosely at the impulse of the expired air; so, in trying to suck, one side only of the mouth acts; in feeding, the lips and cheek are powerless, and, on account of paralysis of the buccinator muscle, food lodges between the cheek and gums."—(Kirkes' *Physiology.*)

12. For *description* of the Eustachian tube, see Cunningham's "Anatomy" (1909), page 762; or Gray's "Anatomy" (1908), page 1163. Its *function* is to keep the atmospheric pressure within the tympanic cavity the same as that on the outside.

13.

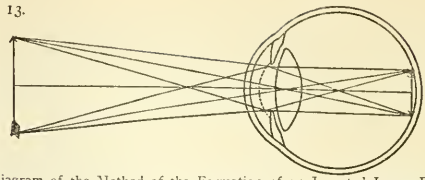

Diagram of the Method of the Formation of an Inverted Image Exactly Focussed upon the Retina. The dotted line is the ideal surface of curvature.

14. *Physical changes characteristic of senility:* Cessation of growth; loss of weight; loss of stature; brittleness of bones; rigidity of cartilages; loss of elasticity of crystalline lens; feebleness and atrophy of muscles; grayness of hair; diminution of sexual activity and power; arteriosclerosis, or other diseased conditions of the arteries; lessened capacity of chest; atrophy and degeneration of digestive glands, kidneys, and testicles or ovaries; slowed reflexes; impairment of the special senses.

15. Polynuclear leucocytes are present normally in the blood; they are decreased relatively in leukemias; and increased in inflammatory and purulent conditions.

CHEMISTRY.

1.

Sulphur trioxide. Phosphoric acid.

2. *Ide* denotes the salt of a hydracid, or a binary compound. *Examples:* KCl, potassium chloride; H_2S, hydrogen sulphide.

Ous denotes either a binary compound with a smaller proportion of the more electronegative element, as SO_2, sulphurous oxid; or a ternary compound, an oxyacid, with less oxygen than is contained in the corresponding *ic* acid, as H_2SO_3, sulphurous acid.

Ic denotes either a binary compound with a greater proportion of the more electronegative element, as SO_3, sulphuric oxid; or a ternary compound, an oxyacid, with more oxygen than is contained in the corresponding *ous* acid, as H_2SO_4, sulphuric acid.

Hypo prefixed to an acid or a salt denotes less oxygen than the "*ous*" acid or the "*ite*" salt.

Per prefixed to an acid or a salt denotes more oxygen than the "*ic*" acid or the "*ate*" salt.

Examples:

HClO = *Hypo*chlor*ous* acid: KClO = Potassium *hypo*chlor*ite.*

$HClO_2$ = Chlor*ous* acid: $KClO_2$ = Potassium chlor*ite.*

$HClO_3$ = Chlor*ic* acid: $KClO_3$ = Potassium chlor*ate.*

$HClO_4$ = *Per*chlor*ic* acid: $KClO_4$ = Potassium *per*chlor*ate.*

3.

	C.	F.
(*a*) Boiling point of water.....	100°	212°
(*b*) Freezing point of water.....	0°	32°
(*c*) Freezing point of mercury.....	—40°	—40°

4. (*a*) *Distillation* is the conversion of a liquid into a gas, followed by the reconversion of the gas into a liquid. *Example:* The distillation of water.

(*b*) A *pentad element* is one that has a valence of five. *Example:* Phosphorus. See graphic formula for phosphoric acid in question 1.

(*c*) *Molecular weight* is the weight of a molecule of a substance as compared with the weight of an atom of hydrogen. It may also be said to be the sum of the weights of the atoms composing the molecule. Thus, the molecular weight of sulphuric acid, H_2SO_4, is (2 + 32 + 64), that is, 98; or 98 times the weight of an atom of hydrogen.

(*d*) A *gas* is that form of matter in which the molecules tend to get away from each other; it has neither definite shape nor definite volume. *Example:* Oxygen.

(*e*) An *acid* salt is one in which only part of the replaceable hydrogen has been replaced by a metal. *Example:* $KHSO_4$, monopotassic sulphate.

5. H_2O_2. *Preparation:* By the action of a dilute acid on sodium dioxide:

$$Na_2O_2 + 2HCl = 2NaCl + H_2O_2.$$

Uses: Disinfectant, antiseptic, and bleaching agent; as an oxidizing agent; for renovating old oil paintings and bleaching hair.

Test: Add freshly prepared tincture of guaiacum and a few drops of a cold infusion of malt; the presence of H_2O_2 is indicated by the appearance of a blue color.

6. NH_3. *Occurrence:* In nature, from the decomposition of animal or vegetable matter containing nitrogen and hydrogen. *Preparation:* By heating solution of ammonium hydroxide:

$$NH_4HO + \text{heat} = H_2O + NH_3.$$

Uses: It is used as a respiratory stimulant, a circulatory stimulant, a counterirritant; it neutralizes acids, making definite salts known as ammonium salts, which are formed by the direct combination of the ammonia with the acid. It is also used in the artificial preparation of ice.

7. IODINE. *Chief sources:* Seaweeds, and in seawater in combination with sodium, potassium, calcium, and magnesium. *Preparation:* From Chili saltpeter, in which it occurs as sodium iodate. this latter is treated with a mixture of sodium sulphite and sodium bisulphite, when the iodine is precipitated as a black deposit:

$$2NaIO_3 + 3Na_2SO_3 + 2NaHSO_3 = 5Na_2SO_4 + H_2O + I_2.$$

Five compounds: Hydriodic acid, HI; Iodic acid, HIO_3; Potassium iodide, KI; Phosphorus triodide, PI_3; Iodoform, CHI_3.

8. SULPHURIC ACID. *Preparation:* By the union of sulphur trioxide and water: $SO_3 + H_2O = H_2SO_4$.

Properties: A colorless, heavy, oily liquid; it has a strong attraction for water, and in combining with it there is an increase in the bulk of the liquids and a rise of temperature; it is a strong corrosive. *Uses:* It is used in all branches of chemical industry and in many industrial pursuits.

9. K_2CO_3 is Potassium Carbonate, or dipotassic carbonate. *Properties:* It is a white, granular, deliquescent, soluble powder, making an alkaline solution. *Chief sources:* Wood ashes and cream of tartar.

10. Magnesium sulphate.

11. Ferric hydroxide may be hurriedly prepared by precipitating solution of ferric sulphate with magnesia. The two solutions should be kept in separate bottles, and when needed they may be mixed and administered. It is used as an antidote in acute arsenical poisoning.

12. GLUCOSE. *Source:* Grapes, honey, diabetic urine. *Test for glucose (in urine):* Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color."—(Witthaus' *Essentials of Chemistry.*)

13. URINE. (*a*) *Specific gravity*, about 1015 to 1025. (*b*) *Reaction*, acid. (*c*) *Color*, yellowish or amber. (*d*) *Constituents:* Water; urea, uric acid, hippuric acid, xanthin, hypoxanthin, creatin, creatinin, extractives; chlorides, phosphates, sulphates (of sodium, potassium, calcium, and magnesium). (*e*) About forty to fifty ounces is voided in twenty-four hours.

14. *Three disinfectants:* (1) Sulphur dioxide, SO_2; (2) Formaldehyde, HCOH; (3) Potassium permanganate, $K_2Mn_2O_8$. One of the best means of fumigating by formaldehyde gas is by Trillat's apparatus, which "allows the solution of formalin to flow in a fine stream through a copper coil heated to redness by a flame beneath, and the gas and vapor passing directly into the room. The apparatus may be operated outside of a room, and the amount of gas liberated depends directly upon the strength and quantity of the solution evaporated."

15. *Relative proportion of water* in: (*a*) Gastric juice, about 99+ per cent.; (*b*) human milk, about 87 per cent.; (*c*) blood, about 78 per cent.; (*d*) Urine, about 95 per cent.

DIAGNOSIS.

1. See French's "Practice of Medicine" (1907), pages 146, 148, 126, and 127; or Osler's "Practice of Medicine" (1909), pages 163 and 107.

2. See French's "Practice of Medicine" (1907), page 284; or Osler's "Practice of Medicine" (1909), page 240.

3. See French's "Practice of Medicine" (1909), page 317; or Osler's "Practice of Medicine" (1909), page 132.

4. See French's "Practice of Medicine" (1907), page 510; or Osler's "Practice of Medicine" (1909), page 726.

5. *Value of a blood count:* Diagnosis may be made of pernicious anemia, secondary anemia, lymphatic leukemia, splenomedullary leukemia, and Hodgkin's disease; also of various inflammatory conditions and conditions in which pus is present. A negative finding is of considerable value. In the first group, the diagnosis is made absolutely by the blood count; in Hodgkin's disease the count is negative; in conditions with pus or inflammations the blood count is of great assistance in arriving at the diagnosis.

6. See French's "Practice of Medicine" (1907), pages 598 and 601.

7. See French's "Practice of Medicine" (1907), page 569; or Osler's "Practice of Medicine" (1909), page 789.

8. See French's "Practice of Medicine" (1907), page 651; or Osler's "Practice of Medicine" (1909), page 604.

9. See Rose and Carless' "Surgery" (1908), page 872.

10. See French's "Practice of Medicine" (1907), page 755; or Osler's "Practice of Medicine" (1909), page 481.

11. See Rose and Carless' "Surgery" (1908), page 1121; or Da Costa's "Surgery" (1908), page 838.

12. See French's "Practice of Medicine" (1907), page 822; or Osler's "Practice of Medicine" (1909), page 539.

13. *Symptoms of pyuria* may be absent, or slight; there may be pain over neck of bladder, in urethra, or in lumbar region; also scalding pain on urination. To confirm diagnosis: Centrifuge the urine and examine with microscope; the addition of a 1 per cent. solution of acetic acid makes the nuclei of the cells more evident. Addition or liquor potassæ to the deposit of pus cells produces a ropy gelatinous mass. A bacteriological examination may show the gonococcus, tubercle bacillus, colon bacillus, typhoid bacillus, or the ordinary pyogenic bacteria.

14. See French's "Practice of Medicine" (1907), page 1118; or Osler's "Practice of Medicine" (1909), page 1048.

15. See French's "Practice of Medicine" (1907), page 953; or Osler's "Practice of Medicine" (1909), page 369.

COMA FROM INTRACRANIAL INJURY.	APOPLECTIC COMA.	ALCOHOLIC COMA.
Deep coma; may have history of onset after fall or injury. Evidence of fracture of vertex or base.	Deep coma; sudden onset. If any injury, only a scalp wound.	Can be aroused by supraorbital pressure unless very profound.
Pupil dilated on side of lesion. Choked disc.	Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Pupils normal or somewhat dilated.
Pulse very slow.	Pulse full and slow, often arteriosclerotic, high-tension pulse.	Pulse more rapid than normal and full.
Respiration slow and stertorous.	Respiration slow and irregular.	Regular respiration.
Temperature higher—101°.	Temperature higher on paralyzed side, but lower in rectum.	May be low or normal.
Urine normal or contains trace of albumin.	Urine contains trace of albumin, but may be same as in uremia.	Normal.
Hemiplegia on opposite side to that of injury. If contusion of brain is also present, may have generalized convulsions.	Hemiplegia with convulsions on one side.	

PATHOLOGY.

1. See French's "Practice of Medicine" (1907), pages 1062 and 1063; or Osler's "Practice of Medicine" (1909), page 924.

2. See Rose and Carless' "Surgery" (1908), page 220; or Da Costa's "Surgery" (1908), page 339.

3. *Syphilitic ulcer:* "The initial lesion first presents small areas of round-cell infiltration in the deeper layers of the skin or mucous membrane, and as a rule in the neighborhood of the blood-vessels. The connective tissue at the same time undergoes proliferative change, and spindle-shaped cells or irregular embryonal connective tissue cells are found mingled with the round lymphoid cells, or surrounding the foci of the latter. Thickening of the blood-vessels may be observed in the later stages or from the very first. The tissue elements of the skin and of the subcutaneous tissue are usually separated by infiltrating liquid, and the latter may loosen the tissues of the surface and cause exfoliation of the superficial epidermis, and thus lead to the development of the primary vesicle or the erosion so commonly seen. The induration of the chancre is probably the result of the sclerosis of the vessels and the general connective tissue hyperplasia, as well as in part due to the tense infiltration of serous liquid."—(Stengel's *Pathology.*)

4. In *lymphatic leukemia* the blood shows: An enormous

increase in the number of white cells, chiefly in the lymphocytes, which may be 90 per cent. of the whole number; the polynuclears are greatly diminished; there are no myelocytes; the red cells are not much affected, but may show a slight diminution in number and in hemoglobin. In *Hodgkin's disease* the blood may be normal or there may be a slight or severe anemia, with diminution of red cells; sometimes leucocytosis occurs. In *Trichinosis* there is a leucocytosis, with a pronounced increase in the eosinophites.

5. *Three varieties of thrombus:* (1) *Red thrombus,* which originates from blood at rest, such as after ligature of the femoral artery for popliteal aneurysm. It is soft, not laminated, consists of a loose network of fibrin which entangles very many red corpuscles and a few leucocytes; it adheres to the vessel wall and later contracts. (2) *White thrombus,* which originates from circulating blood, such as is found in an aortic aneurysm; it is firmer than the above, it is laminated, it is dense; it is composed chiefly of leucocytes, but red cells are also present, as well as fibrin network and some granular material, probably derived from broken down blood platelets. (3) *Parietal thrombus* is one which adheres to the vessel wall, but only partially occludes the blood-vessel, in opposition to an *obstructive or obliterating thrombus,* which absolutely obstructs the blood channel.

6. See Osler's "Practice of Medicine" (1909), page 968.

7. See French's "Practice of Medicine" (1907), page 1030; or Osler's "Practice of Medicine" (1909), page 902.

8. In *acute metritis* "the uterus is enlarged, congested, soft, plastic, and infiltrated with the inflammatory exudate. Microscopically, the chief changes are observed along the bloodvessels and lymphatics, where a round-cell infiltration, more or less marked, can be observed. Here and there small abscesses may be seen. The muscle cells may show signs of degeneration. In exaggerated cases of puerperal metritis, gangrene of the tissues may occur. Thrombosis of the uterine sinuses and veins is common, and suppurative lymphangitis is frequent in and about the organ."—(McFarland's *Pathology.*)

9. *Metastasis* is the transfer of some pathological condition from one part of the body to another, not immediately connected with it. The most frequent channels of metastasis are the blood and lymphatics.

BACTERIOLOGY.

10. A *spirillum* is a rod-shaped bacterium spirally twisted, and somewhat resembling a corkscrew. *Example:* The spirillum of Asiatic cholera, which is motile, flagellated, liquefying, non-sporogenous, non-chromogenic, aërobic, parasitic, and saprophytic, stains with the ordinary dyes, but is Gram negative, and causes Asiatic cholera.

11. The *Streptococcus pyogenes* is a micrococcus, of spherical shape, and arranged in chains of about thirty or forty cocci (in liquid media), but the chains are much shorter in solid media. Each coccus is about one-half to two mikrons in diameter. It is not motile, does not form spores, does not liquefy gelatin, and stains readily with the ordinary anilin dyes, and by Gram's method. It has been found in meningitis and erysipelas.

12. The microorganism of influenza is Pfeiffer's bacillus. This is a small, non-motile, non-flagellated, non-sporogenous, nonliquefying, non-chromogenic, aërobic bacillus, staining by ordinary stains, but Gram negative; its cultivation requires the presence of hemoglobin.

13. The *characteristics of the bacillus of diphtheria:* The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are nonmotile, and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue. *Two associated organisms:* Streptococcus pyogenes and micrococcus lanceolatus.

14. Lobar pneumonia is usually caused by the *Micrococcus lanceolatus,* better known as the *Diplococcus lanceolatus,* or the pneumococcus of Fraenkel and Weichselbaum. *Process of staining:* Spread a cover glass with a smear containing the bacteria, dry it, then fix it in a flame. It can then be stained for from five to ten minutes in Ehrlich's solution; it is then to be washed in water and afterwards immersed in Gram's solution for two or three minutes. It is then washed in 95 per cent. alcohol. While in the Gram's solution the specimen is very dark brown, but it becomes violet or blue again on application of the alcohol.

15. *Four sources of infection:* (1) The air; (2) food or water; (3) wounds; (4) unclean implements of all kinds. *Their comparative importance* cannot be estimated, because certain microorganisms have *their special* avenues of infection, thus the typhoid bacillus enters by the digestive tract

SURGERY.

1. See Rose and Carless' "Surgery" (1908), page 1318; or Da Costa's "Surgery" (1908), page 1046.

2. See Rose and Carless' "Surgery" (1908), page 261; or Da Costa's "Surgery" (1908), page 124.

3. See Rose and Carless' "Surgery" (1908), page 1132; or Da Costa's "Surgery" (1908), pages 138 and 142.

4. Tetanus is to be feared. See Rose and Carless' "Surgery" (1908), page 235; or Da Costa's "Surgery" (1908), page 251.

5. See Rose and Carless' "Surgery" (1908), page 195; or Da Costa's "Surgery" (1908), page 302.

6. See Rose and Carless' "Surgery" (1908), page 1311; or Da Costa's "Surgery" (1908), page 1218.

7. *Indications for osteotomy:* Deformities of bones and joints (such as result from congenital conditions); diseases of bones and joints, followed by curvature or angularity; ankylosis; and malunion following fracture.

See Rose and Carless' "Surgery" (1908), page 448; or Da Costa's "Surgery" (1908), page 612.

8. See Rose and Carless' "Surgery" (1908), pages 621 and 622; or Da Costa's "Surgery" (1908), pages 587 and 590.

9. See Rose and Carless' "Surgery" (1908), page 759; or Da Costa's "Surgery" (1908), page 763.

10. See Rose and Carless' "Surgery" (1908), pages 989 and 991; or Da Costa's "Surgery" (1908), pages 826 and 829.

11. See Rose and Carless' "Surgery" (1908), page 311; or Da Costa's "Surgery" (1908), page 361.

12. See Rose and Carless' "Surgery" (1908), page 446; or Da Costa's "Surgery" (1908), page 611.

13. See Rose and Carless' "Surgery" (1908), pages 1226 and 1227; or Da Costa's "Surgery" (1908), page 1187.

14. TRACHOMA. *Subjective symptoms:* "More or less photophobia, lachrymation, itching and burning sensations, feeling of foreign body, pain, and visual disturbance. In a good many cases there are no subjective symptoms."

Objective symptoms: "Swelling of the lids, narrowing of the palpebral aperture, and drooping of the upper lid (from weight and swelling). There is a variable amount of mucopurulent discharge, marked in recent cases, scanty in chronic forms. The conjunctiva of the tarsus and fornix is reddened, thickened, and uneven, on account of hypertrophy and the occurrence of granules. The ocular conjunctiva is often somewhat injected."

Treatment "consists in an attempt to reduce the inflammatory symptoms and secretion, and to check and remove hypertrophy of the conjunctiva, thus shortening the duration and diminishing the liability to conjunctival cicatrization and to sequelæ. This is accomplished either by the use of certain irritating applications, or by mechanical (surgical) means. *"Irritating applications:* Sulphate of copper in the form of a crystal or pencil is the favorite local application. Nitrate of silver (1 or 2 per cent. solution), glycerole of tannin (5 to 25 per cent.), and the alum stick are also employed. *Mechanical (surgical) treatment* includes expression, grattage, excision, curetting, electrolysis, *x*-rays, and galvano cautery."—(May's *Diseases of the Eye.*)

OBSTETRICS AND GYNECOLOGY.

1. See Williams' "Obstetrics" (1909), page 611; or Hirst's "Obstetrics" (1909), page 267.

2. See Williams' "Obstetrics" (1909), pages 167 and 185; or Hirst's "Obstetrics" (1909), page 180.

3. See Williams' "Obstetrics" (1909), page 199; or Hirst's "Obstetrics" (1909), page 188.

4. See Williams' "Obstetrics" (1909), pages 201, 343, and 355; or Hirst's "Obstetrics" (1909), page 371.

5. See Williams' "Obstetrics" (1909), page 190; or Hirst's "Obstetrics" (1909), page 204.

6. See Williams' "Obstetrics" (1909), page 414; or Hirst's "Obstetrics" (1909), page 811.

7. See index to Williams' "Obstetrics" or Hirst's "Obstetrics," under heading "Dystocia."

8. See Williams' "Obstetrics" (1909), page 915; or Hirst's "Obstetrics" (1909), page 256.

9. See Williams' "Obstetrics" (1909), page 298; or Hirst's "Obstetrics" (1909), page 343.

10. The *indications for version* are: (1) In transverse presentations; (2) in placenta prævia; (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsed

funis; (6) in sudden death of the mother, and (7) in any case where speedy delivery is imperative.

See Williams' "Obstetrics" (1909), pages 434, 437, and 439; or Hirst's "Obstetrics" (1909), page 829.

11. See Hirst's "Obstetrics" (1909), pages 807 to 873.

12. See Williams' "Obstetrics" (1909), pages 535, 525, and 541; or Hirst's "Obstetrics" (1909), pages 628, 630, and 635.

13. See Williams' "Obstetrics" (1900), page 289; or Hirst's "Obstetrics" (1909), page 419.

14. *Vaginitis* is a condition of inflammation of the vagina. It is characterized by redness, swelling, pain, heat, irritation, and increased secretion. There may be frequent and painful urination. *Treatment* consists in rest, cleanliness, douches, the application of soothing lotions, and removal of any cause; salines and anodynes are also indicated. *Vaginismus* is a condition of painful and spasmodic contraction of the vaginal orifice, which renders coitus either painful or altogether impossible. The slightest touch causes painful spasms, and examination may be impossible without an anesthetic. The *treatment* consists in removing the cause when possible, tonics and general constitutional treatment, dilatation of the vaginal orifice; local application of a 5 per cent. solution of cocaine will relieve the hyperesthesia and allow coitus. The condition is sometimes incurable.

15. CHRONIC ENDOMETRITIS. *Causes:* Debility, repeated pregnancies, lacerations, and subinvolution of uterus, fibroids, gonorrhea, or sepsis. *Pathology:* The mucous membrane is swollen, red, and soft; blood extravasations may be found in some places; the cervical glands may become occluded and form cysts; mucous polypi or other excrescences may be present; the os may be eroded or granular. Microscopical examination shows a great development of the utricular glands, round-cell infiltration, and dilated blood-vessels. Later the mucous membrane becomes atrophic, and the glands are replaced by connective tissue fibers. *Symptoms:* Neuralgic, bearing-down pains; cramps; dysmenorrhea; irritable bladder; menorrhagia or metrorrhagia; leucorrhea, which may be blood-stained or purulent; profuse hydrorrhea; loss of appetite, constipation, dyspnea, palpitation, sterility. The uterus as a whole is abnormally tender; the uterine cavity is enlarged; the external os is patulous, and shows a tendency to bleed on being touched. *Diagnosis:* "In *lumboabdominal* neuralgia the uterus may be sensitive, especially in the region of the internal os, but there is no leucorrhea or hemorrhage. A *myoma* is often accompanied by these symptoms, but then the tumor can be felt. A *fibroid polypus* can be diagnosticated with the sound. The differentiation from beginning *carcinoma* may be difficult. In this the neoplasm is so friable that a small portion of it may be detached by the mere examination. Around the new growth is an indurated ring as hard as a board. Sometimes pieces of the neoplasm may be expelled spontaneously from the interior of the uterus. Bleeding occurring after the menopause is very suspicious. Pain need not be present. If there is any doubt, a small piece should be cut out of the cervix, or scrapings gained by curettage of the cavity of the uterus. These should be hardened and sections examined with the microscope, when the different histological composition will settle the question. A bloody, purulent, offensive discharge may be found in endometritis, and is not sufficient for the diagnosis of malignant disease."—(Garrigues' *Gynecology.*)

HYGIENE AND SANITATION.

1. *Functions of vegetable acids:* They are converted into carbonates, which aid in maintaining the alkalinity of the blood and other fluids; they also tend to prevent scurvy, and furnish a small amount of heat and energy.

2. In *collecting and storing rain water for drinking:* The first flow should be allowed to run to waste; this is to ensure cleanliness. The cisterns for storage should allow of easy inspection and cleansing; they should be kept covered so as to exclude dirt, dust, insects, animals, and light; overflow pipes should discharge into the open air and not into the sewer, and the opening should be covered to keep out small animals and foreign matter; the cisterns should be well ventilated, and regularly and thoroughly inspected.

3. *General rules for bathing:* One should not bathe within two hours after a meal, or when tired or heated; avoid chilling; do not bathe in the open air if the body feels chilly or the hands and feet become numbed; those subject to giddiness, fainting, or cardiac discomfort should not bathe out of doors. *Cold baths* have a tonic and stimulating effect, the pulse is increased in force and frequency, the respirations are deeper. Cold baths should not be taken by those suffering from organic heart disease or who become chilled thereby, or by women in the later months of pregnancy.

4. The desks should be so placed that the light comes from the *left* of the pupils. If it comes from the *right*, shadows are cast across the writing; if it comes from *both sides*, double shadows are cast; if it comes from *behind*, shadows of the body are cast on the writing or work; light from the *front* is very trying to the eyes.

5. Water can be freed from bacteria by the use of a Pasteur-Chamberland filter, or a Berkefeld filter; also by sterilization by heat—boiling.

6. The sewer should be circular or egg-shaped in section; it should be laid in as straight a line as possible, and with a regular fall; the junctions should be oblique, so that the sewage may enter in the direction of the flow; if it curves, it should do so with a very wide sweep; it should be made of well cemented brickwork, with the interior smoothly finished; there should be ample arrangements for ventilation, flushing, and inspection; the fall should not be too great or too rapid, or the water will run away rapidly and the solid matter will be left behind.

7. Unripe fruit is unwholesome because: (1) It causes malfermentation in the stomach and intestines; (2) it causes colic, cramps, pain, diarrhea, and vomiting; (3) it may cause gastritis, or choleraic diarrhea; (4) the tannin and vegetable acids which it contains are very astringent and acid. Fruits are valuable as food because they furnish nutriment, convey water to the system, relieve thirst, stimulate the appetite, improve digestion, give variety to the diet, introduce various salts and organic acids which improve the quality of the blood and react favorably upon the secretions.—(From Thompson's *Dietetics.*)

8. A milk epidemic is characterized by the suddenness with which it makes its appearance, the sufferers being for the most part attacked at about the same time. The infected houses will be found to have been supplied, almost without exception, by the particular milk vendor whose supply is at fault; but it will occasionally happen that infected houses are discovered to which milk has been supplied by a different vendor, this circumstance being often due to the fact that the vendors on their rounds very commonly buy small quantities of milk from each other. Sometimes valuable corroborative testimony implicating the milk is forthcoming in the circumstance that some of those in the infected households, who have consumed no unboiled milk, have escaped; and that households supplied from the implicated dairy, but in which no unboiled milk is consumed at all, have entirely escaped.—(Parkes' *Hygiene.*)

9. *Koumyss* is an effervescing fermented liquor, originally made from mare's milk; but it is now made from cow's milk, with sugar of milk, and allowed to ferment in open tanks, the casein and butter are skimmed off, and the koumyss is bottled during fermentation.

Kefir is a fermented drink made from milk by the addition of a special mushroom-like ferment. It contains about four times as much albuminoids (casein, etc.) as koumyss.

10. *How* antitoxin produces immunity and effects cure is not known, but *theories* deduced from observed facts are as follows: "As the various pathogenic bacteria produce the causative toxins of their respective diseases, so the organic cells of the body, reacting under the stimulus of the poisons thus introduced, immediately proceed to elaborate defensive bodies, which if produced in sufficient quantity will neutralize the effects of the toxins. Residual antibodies remaining in the blood after recovery render the animal immune for a time against the disease. The immunizing and curative effects obtained by the injection of the blood serum of an immunized animal into the circulation of another animal are due either to direct chemical neutralization of the toxins themselves by the antibodies so introduced (Behring, Kitasato), or to a particular influence exerted by the antibodies upon the living cells of the organism which, being affected in two opposite directions, remain neutral to the disease (Buchner). Some authorities hold that these results are due to the conjoint action of leucytic and chemical forces. Ehrlich's side-chain theory assumes that every toxin contains toxophore molecules having direct toxic action, and haptophore molecules which combine the toxophores with a similar combining group of molecules in the tissue cell of the attacked organism. The tissue cell molecules being destroyed by the toxophores, a rapid and profuse regeneration of similar molecules occurs in side chains, and these molecules overgrowing are carried into the circulation, becoming the antitoxin, which acts by combining with the haptophores of newly arrived toxin, using up their combining power before they can reach the tissue cells."—(Potter's *Materia Medica*, etc.)

11. *For disinfecting ships and cargoes*, there are used:

Formaldehyde; sulphur dioxide, or sulphurous acid; live steam; acid bichloride of mercury. For method of disinfecting by formaldehyde, see above, *Chemistry*, 14

12. *The principal means of preventing the spread of contagious diseases in schools*, are: Regular and efficient inspection by physicians; prompt exclusion and isolation of anyone suffering from a contagious disease, or coming from a house where such disease is; compulsory vaccination; compulsory notification of all infections and contagious disease; individual towels, drinking vessels, and other implements; children who have had a contagious or infectious disease, or who have come from a house where such disease prevailed, should not be readmitted to school until sufficient time has elapsed since the occurrence of the last case to insure safety.

13. Tuberculosis, trichinosis, tape-worm, ptomaine poisoning, echinococcus disease, and anthrax.

14. *Malaria:* "It has ever been held that the most intimate relation exists between the soil and malaria, especially prominent in districts abounding in marsh lands. It has been noticed repeatedly that in malarious countries the upturning and excavation of wet or damp soil are commonly followed by the occurrence of the disease among the laborers so engaged; that infection is more common among those who go about at night, and especially among those who sleep out of doors; and that the draining of marsh lands is often followed by the disappearance of the disease. All of these facts are compatible with the theory of transmission by mosquitoes, and it is now accepted generally that malaria is connected with soil conditions only in so far as the latter permit the breeding of the specific mosquitoes."

Yellow Fever: "There is no evidence of connection between the soil and outbreaks of yellow fever, although for many years such a relation was assumed to exist. The disease is mosquito-borne."—Harrington's *Practical Hygiene*.

15. (*a*) In *beef*, protein; (*b*) in *wheat*, carbohydrates; (*c*) in *eggs*, protein and fats, predominate.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. ..
Arizona*	Ancil Martin, Phoenix	Phoenix	Oct. 3
Arkansas	F. T. Murphy, Brinkley	Little Rock	Nov. 8
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	..
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Oct. 4
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov. 14
Delaware	J. H. Wilson, Dover	Dover	Dec 13
Dist. of Col'bia.	Geo. C. Ober, Washington	Washington	Oct. 11
Florida*	I. D. Fernandez, Jacksonville	Palatka	Nov. 9
Georgia	T. H. Goss, Athens	Atlanta	Oct. 11
Idaho*	W. F. Howard, Pocatello		Oct. 4
Illinois	J. A. Egan, Springfield	Chicago	Oct. ..
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Jan. 10
Iowa	Louis A. Thomas, Des Moines	Des Moines	..
Kansas	H. A. Dykes, Lebanon	Topeka	Oct. 11
Kentucky	J. N. McCormack, Bowling Green	Louisville	..
Louisiana	E. L. McGehee, New Orleans	New Orleans	Oct. 18
Maine	F. W. Searle, Portland	Portland	Nov. 8
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 13
Massachusetts*	E. B. Harvey, State House, Boston	Boston	Sept. 13
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Lansing	Oct. 11
Minnesota	W. S. Fullerton, St. Paul	St. Paul	Oct. 4
Mississippi	S. H. McLean, Jackson	Jackson	Oct. 11
Missouri	Frank B. Hiller, Jefferson City	Jefferson City	Sept. ..
Montana*	Wm. C. Riddell, Helena	Helena	Oct. 4
Nebraska	C. A. Carr, Lincoln	Lincoln	..
Nevada	S. L. Lee, Carson City	Carson City	Nov. 2
N. Hampshire	Henry C. Morrison, State Library, Concord	Concord	Jan. 3
New Jersey	H. G. Norton, Trenton	Trenton	Oct. 18
New Mexico	J. A. Massie, Santa Fe	Santa Fe	Oct. 10
New York	C. F. Wheelock, Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo	Sept. 27
N. Carolina	B. K. Hays, Oxford	Charlotte	June 14
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	Oct. 4
Ohio	Geo. H. Matson, Columbus	Columbus	Dec. 13
Oklahoma*	F. P. Davis, Enid	Guthrie	Oct. 11
Oregon	B. E. Miller, Portland	Portland	Jan. 3
Pennsylvania*	N. C. Shaeffer, Harrisburg	Philadelphia, Pittsburg	Dec. ..
Rhode Island*	G. T. Swarts, Providence	Providence	Oct. 6
S. Carolina	H. H. Wyman, Aiken	Columbus	June 13
S. Dakota	H. E. McNutt, Aberdeen	Watertown	Jan. 11
Tennessee	C. A. Abernathy, Pulaski	Memphis, Nashville, Knoxville	May 28
Texas	R. H. McLeod, Palestine	Palestine	Nov. 22
Utah	R. W. Fisher, Salt Lake City	Salt Lake City	Oct. 3

Wisconsin	J. M. Beffel, Milwaukee	Milwaukee	Jan. 10
Wyoming	S. B. Miller, Laramie	Laramie	Oct. 12

* No reciprocicity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of August 6, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	674	137
Diphtheria	214	17
Measles	179	11
Scarlet Fever	85	2
Smallpox	1	—
Varicella	9	—
Typhoid Fever	96	9
Whooping Cough	55	9
Cerebrospinal Meningitis	6	5
Malarial Fever	—	—
Totals	1,319	190

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, during the week ended August 5, 1910.

		CASES.	DEATHS.
CHOLERA.			
India, Calcutta	June 5–11	..	31
Madras	June 18–24	..	1
Java, Batavia	June 5–18	40	31
Present in extreme eastern part.			
Samarang	June 18	..	Still pres't.
Russia, Baku, government	June 19–25	7	5
Present in districts of Igoumen, Mazir, Pinsk, Retchitsk, and Sloutsk.

THE INFLUENCE OF THE USE OF THE AUTOMOBILE UPON THE UPPER AIR PASSAGES.*

By D. BRYSON DELAVAN, M.D.,

NEW YORK.

The almost universal adaptation of the motor vehicle for pleasure as well as for business purposes implies the fact that countless numbers of people come within its influence, some as actual users of it, and some as mere spectators of its use. It becomes, therefore, a matter of great human interest, of actual importance to the State, to know the effects of the new means of locomotion upon the physical welfare of the public. To that end this subject is presented, in the hope that discussion of it may bring definite and useful results.

The influence of the automobile upon the mind, the morals, and the physical being of those who use it presents questions of interest well worthy of study. Already more or less has been written concerning these topics. Its effects, however, upon the upper air passages do not not seem to have attracted serious attention, and yet offer opportunity for considerable investigation and comment.

The automobile may effect both him who uses it and him who does not. The exposure to one who rides in an open vehicle may bring about effects which would not endanger the one riding in a limousine. The chauffeur may also be exposed to dangers peculiar to his position. As to the man who walks, it is his part to inhale the fumes which poison the atmosphere of our best avenues and to either be driven from his home by the noise of the autos or choked by the dust which is raised by them and blown in his direction.

If the experience of other occupations which are known to be injurious to the air passages is any criterion, it is time that we had undertaken to consider the influence of the automobile.

The factors which may work injury may be divided into two groups, namely, first, conditions relating to the air itself, and, second, impurities carried by or suspended in the air. The first includes temperature, air currents, and air pressure; the second, dust and smoke. Sudden and violent changes of temperature are often encountered by the motorist. Exposure to strong draughts is also a common experience, the draughts being due to natural air currents or to the rapid motion of the car. Where the car is speeding in the face of a breeze the resulting increase of air pressure must be considerable.

Sudden change of temperature or rapid radiation of body heat due to exposure to air currents may cause chill, and, indirectly, the latter's well-known results upon the breathing apparatus. Increased atmospheric pressure, especially when combined with cold, must of necessity exert important influences upon the respiratory region, from the nasal cavities and their communicating passages to the ultimate vesicles of the lungs. Examples of this are common. Thus, during the height of the great blizzard of 1888, many persons attempted to walk from their places of business to their homes, facing the storm. The number of those whose air passages suffered injury was incredible, while the variety of affections included a fair proportion of the inflammatory conditions possible to the ears, nasal region, pharynx, larynx, trachea, bronchi, and lungs. Deaths were numerous, while there are many patients suffering from chronic disorders today who date the origin of their troubles from that or some similar experience. A rate of thirty miles an hour constitutes a stiff breeze, while sixty miles represents a gale. These facts we know, and yet easily forget in the exhilaration of the ride.

Studies made with regard to the actual resistance of the air in speeding give interesting results. It is stated that at speeds below 20 miles an hour the effect of wind resistance is too slight to be measurable. Considering surfaces at right angles to the normal plane of travel of the automobile, resistance begins to show at about 15 miles an hour. It increases slowly, reaching about 2½ pounds a square foot at 30 miles an hour. Higher speed results in rapidly increasing rate of resistance until at 60 miles an hour the pressure is about 13 pounds. At 90 miles it has increased to about 29 pounds.

If these observations are correct, air pressure in connection with the use of the automobile is not a negligible factor, especially when related to its influence upon the air passages. Of course, it must be remembered that the rate of pressure may be greatly increased by adding the force of a head-wind to the speed of the machine. Thus, a speed of 30 miles against a 20-mile breeze would create a 50-mile pressure. While there may be some conditions of the lungs in which exposure to a moderate increase of air pressure for a limited amount of time would be beneficial, there must be many cases in which great increase of pressure, or pressure long continued, would result in injury, even to a healthy lung. In certain pathological conditions, such, for example, as emphysema, the risk is obvious.

The second injurious factor is the impurities which may be inhaled with the inspired air. These consist of dust, of smoke, and of other matters, among which may be mentioned plant products and small insects. The deleterious effects of dust upon the air passages are obvious. Those engaged in dusty occupations such as emery grinding, certain

*Read before the American Laryngological Association at its Thirty-second Annual Meeting, Washington, D. C., May 3, 1910.

kinds of stone cutting, the handling of furs, and the manufacture of certain powders and fabrics, almost invariably suffer. Smoke also irritates them, and the smoke of the auto is especially irritating.

Another source of irritation is one not generally thought of, but, in the experience of the writer, of sufficient importance to warrant attention. I refer to the presence in the air at certain times and places of large numbers of small winged insects, and, also, to the products of plants, shrubs, and trees, which, at certain seasons of the year, fill the air, especially in the neighborhood of their production. Mosquitoes and gnats in great variety are frequently encountered after sundown in passing over country roads, especially if the latter run through growths of trees or near swamp lands. Insects of larger type may endanger the eyes. The smaller ones not only offer the same possibility, but may readily be inhaled, either into the nasal cavities or into the larynx or trachea. Any one who has experienced such an accident will remember its irritating effects, which may not only be severe for the present, but may leave behind the possibilities of serious trouble.

Dust may be irritating from its mechanical properties. Thus fine sand, as has often been demonstrated in its effect upon stone workers, has injurious properties which depend upon the sharp cutting qualities of the particles of silicate of which the dust is composed. Other kinds of dust may be harmful, not only by reason of the peculiar shape of the particles, but, also, because of the irritating nature of the substance itself, as, for instance, in the case of the horse droppings and the many other accompaniments of ordinary street dust.

With regard to the equipment of the motorist, every conceivable appliance and convenience is provided for him. This is especially true of protections for the eye, which are supplied by the shops in great variety. In considering this, however, it at once appeals to one as strange that protection of the breathing apparatus against dust and severe winds seems to be neglected. I have searched many shops, but have never yet found a satisfactory respirator, nor do I know anything in recent scientific literature bearing upon the subject. Almost the single exception to this statement is the face guard used in racing, for protection against the wind. This is of simple pattern and construction, and for its purpose is said to be effective. It can hardly be entirely successful, however, in excluding dust. For the latter purpose none of the old-fashioned respirators, such as have been worn in London for many years for protection against fog, nor those of the Morrell Mackenzie type, for preventing the inhalation of dust by emery grinders, stone workers, and the like, are satisfactory. The majority of those who attempt any protection at all are ladies, who use chiffon veils in which they envelop the entire head. This method, of course, offers a certain amount of relief to the air passages, but it can not be considered ideal.

The lack of attention which has been given to the subject of respirators would imply that dust is an unimportant factor. In regions where the roads are well cared for and properly oiled this is to some extent true. Any one who has seen automobile parties coming in after long runs in dry weather, through an open country, will remember the extent to which everything pertaining to the motor and its occupants has been covered with dust. This is especially true of many districts in Europe, where oiling of the roads is unknown, and where limestone or other comparatively soft material used in making the roads has furnished a fine powdery grit, which rises in dense clouds and penetrates everywhere.

The introduction of the "wind shield" has resulted in modifying the effect of wind currents with considerable success. Roe states that since it has been more generally used diseases of the nasal sinuses among autoists have been distinctly less common. Shurly calls attention to the fact that habitual speeding develops the so-called "automobile face," a characteristic of which is the open mouth. Such persons, he believes, are particularly liable to infections.

In dealing with the question of automobile smoke several factors are to be considered. The irritating particles may, perhaps, be too small in size to exert much mechanical influence upon the mucous membranes, but their quality may be such as to cause decided irritation. Added to this is the pungent odor which in itself may be excessively irritating.

While some may doubt the harmfulness of the emanations from the exhaust of the automobile, it is hardly possible to suppose that they can be entirely without effect. Even to healthy membranes their presence in the air is consciously annoying. Where the mucous linings of the air passages are already, for any reason, in a sensitive condition, there is no question, if we may rely upon persons of intelligence and experience, who have considered the matter, that the automobile fumes have caused them painful annoyance at the time and in some cases long continued and severe after irritation. This is often observed in cases of ear trouble, due to Eustachian catarrh, while patients suffering from asthma, bronchitis, tuberculosis, and the like are undoubtedly affected by it.

Without question mucous membranes already irritated are more especially liable to infections of a general nature; even supposing the smoke and gases from the auto to be sterile, their ultimate contributory effects may easily become important, particularly when combined with the notoriously microbe-laden dust of city streets.

Theoretically considered, the use of the automobile should be productive of a decided increase in the average of respiratory ills. Whether or not it has actually so resulted is a question. Taking up the causes of injury, we will first refer to chill. This may be acquired through unsuitable or insufficient clothing, or through clothing improperly applied. Not only should the body be protected, but the limbs should be carefully covered, especially in open motors. A coat, otherwise warm, may be cut too low in the collar. The idea that undue exposure of the neck and throat tends to strengthen the parts is a popular fallacy. No such custom prevails with the Eskimos and others of exposed life dwelling in cold latitudes. No part of the body would seem to demand more careful protection than that adjacent to the top of the sternum, where center the most important blood vessels of the body, many of them within short distances of the outer world. A coat which does not properly protect the throat is like a roofless house. Any one who has skated, or has sailed an ice-boat in very cold weather, or who has had experience in mountain climbing at high altitudes, will readily understand this. In motoring, neither extreme cold nor great altitudes are necessary to bring about conditions which rapidly lower the body temperature. As with the neck so with

the feet. Low shoes, unprotected ankles, and want of rugs may quickly work disaster. Some of the head coverings used are admirable. Others are exceedingly bad, comfort and safety being sacrificed to appearance, with no attempt to protect and shield the face and neck. The subject of proper underclothing must also be considered. The wearing of an abdominal band is considered by many experts a great protection against chill. It is easy to become chilled in an automobile when one enters it after leaving a warm room, even when well protected with clothing. Still worse to ride in an open machine in the country, fresh from an overheated train and with thin clothes. This latter situation sometimes confronts the city consultant when he is called out of town.

Apparently the worst case is that of the chauffeur who, in the effort to replace a tire or repair some injury, works himself into profuse perspiration and then upon the driver's seat makes up lost time against a cold breeze. Such exposure should be prolific of throat and lung trouble. As a matter of fact, it does not seem to be. This may be accounted for by the youthful vigor and personal power of resistance of those who engage in the work of motor driving, as well as by the health-giving effects of a life of abstinence and of activity in the open air.

Having considered the above-mentioned factors, the next step would be to study their effects upon the upper air passages in healthy individuals.

To that end we have endeavorer to make a collective investigation of the subject, and have taken the chauffeur as the basis of study, selecting him because, as a professional, he devotes a maximum amount of time to his work; because his position is more exposed than that of others; and because he may be supposed to represent a fair type of the average healthy individual. In order to gain the most reliable information possible we have interviewed the medical departments of four leading life insurance companies. All agree that the subject should be, and is being, investigated, but state that it has only lately come up, that nothing less than a large collection of statistics will be of value, and that the length of time which has elapsed since the matter was taken in hand is too short to admit of reliable deductions and final scientific results. As far as their observations have gone, up to the present time, none of them have been able to notice any special effect of the use of the automobile upon the upper air passages. One of the companies states that while the mortality rate is greater in these cases than with ordinary drivers of vehicles, this is owing to accident and not to disease, and has nothing to do with the real object of our investigation. It makes no extra rate for risk of illness to chauffeurs. It aims to accept only chauffeurs of good standing and of temperate lives, and it believes that any special risks of illness to which they may be subjected are counterbalanced by the non-use of alcoholics and by the life in the open air. Another company regards the chauffeur as not inferior as a risk, and accepts him on equal terms with others of his general grade. A third agrees substantially with the above. In the case of the fourth company an excess rate of one-half of one per cent. was formerly charged chauffeurs. Lately, this excess has been removed and they are taken at the usual rates.

In short, the medical departments of these companies, the largest and most important in the country, have not found that chauffeurs are apparently more liable to the serious respiratory diseases which threaten life than are coachmen. Both, of course, are apt to suffer from pneumonia due to exposure, one of the few conditions likely to come to the notice of life insurance authorities. Diseases not directly fatal, such as sinusitis, would probably not be reported to them. It is desirable that a systematic investigation be made to determine the influence of the automobile upon all respiratory conditions. Finally, if it should appear that they are actually productive of irritation in cases where the condition of the air passages is normal, it would be easy to appreciate their influence upon special conditions of the respiratory tract likely to be aggravated by them.

We will now consider what some of these conditions are. A good illustration would be offered by a case of acute coryza. In this affection it is prerequisite to the successful treatment of the case that the patient be kept in an even temperature, and that he be allowed to breathe pure air. The treatment also demands that the surface of the body be protected from chill. We secure quietude and warmth by sending the patient to bed. It will readily be seen how exposure in an automobile apparently violates all of the first principles of treatment.

That this criticism is not theoretical may be amply proved by common experience. In cases where there is any tendency to involvement of the nasal sinuses in such acute attacks, automobile riding offers every possible element of danger, including the special risk from increased air pressure of forcing elements of infection into the sinuses or into the Eustachian tubes.

The prevalence of sinus disease and of acute infections of the ear in recent years has been attributed to the influence of grippe. In the treatment of these cases, however, experience demonstrates that a patient taken in hand at the early part of the attack, placed under proper conditions and given suitable treatment will generally escape serious trouble. Even if the sinuses have been invaded, a few days will generally suffice to check the inflammation and cure the case. Lack of treatment and of protection, however, and, above all things, exposure to inclement weather, will not only remove the possibility of spontaneous cure which is often present, but in countless instances has aggravated the trouble to the extent of causing infection of other sinuses, intensifying the symptoms and thereby prolonging the subsidence of the attack, or creating complications of the gravest nature. It is just such cases which lapse into chronic conditions, often presenting the greatest difficulties and the most serious dangers. In chronic disease of the sinuses, incautious motoring may expose the patient to especial risk. The same is true in cases of old suppurative conditions of the ear, for reasons too evident to need explanation.

The effect of automobile riding upon the symptom of tinnitus is an interesting and important study. In a patient subject to this phenomenon it may be laid down as a general axiom that the better the condition of the body in general and of the neighborhood of the ears in particular, the less the tinnitus will be in evidence. Naturally, any increase in the tinnitus would imply some additional irritation in the ears or in those parts irritation of which will produce reflexes resulting in tinnitus. It is a common experience of the victims of tinnitus to find that the ringing in the ears is increased by riding

in an automobile. This is especially the case if the ears are unprotected. Such increase may be due either to the irritation of the air currents upon the tympanum, to the results of air pressure in those whose Eustachian tubes are clogged, or to hyperemia of the nasopharyngeal membranes with extension into the Eustachian tubes. Patients susceptible to increased tinnitus, therefore, should be warned of the effect of the automobile, and if they ride should be urged to so protect themselves that the ears will not be endangered. At the very least, the wearing of a cotton plug in the external auditory canal should be enjoined.

In acute catarrhal conditions in general of the air passages motoring would seem to be contraindicated. In many subacute and chronic catarrhal conditions, however, it appears to be distinctly advantageous. In my own experience many such cases have been benefited, and more than one patient of long standing has been cured.

In bronchitis, asthma, and emphysema the rules which would obtain with regard to the avoidance of sudden changes of temperature and exposure to strong winds would be applicable to the use of the automobile.

The same may be said with regard to pulmonary tuberculosis. Several cases have been reported to me in which bronchial asthma, vasomotor coryza, and hay fever have been markedly relieved by it.

The question, however, of the influence of the automobile upon those inclined to throat and pulmonary tuberculosis is another interesting topic. An abundance of fresh, invigorating air should be beneficial. Draughts, sudden changes of temperature, dust, smoke, and irritating gases must, of course, be avoided. A case has been reported to me of a lady who made a motor trip from New York to Chicago and back again in very dry weather. She left apparently in good health and returned with well-marked pulmonary tuberculosis. The investigations of David Twichell have shown that the tubercle bacillus quickly succumbs to sunlight. It is unlikely that the patient above mentioned contracted tuberculosis from the dust of the roadways. Possibly the disease may have been latent or unsuspected when she started and was developed by the excitement and fatigue of the journey, coupled with the mechanical irritation to the respiratory membranes of the dust.

Again, the membranes having been irritated by dust, the germ may have been acquired in some lodging place upon the way.

Possibly this isolated case represents a rare accident in which the influence of the automobile is not entirely evident. In any event it would seem worthy of notice.

Good authorities, of course, interdict motoring in tuberculous subjects whose temperature is above normal. In certain cases, particularly of the nervous, restless type, the mild stimulation of the circulation, deep-breathing, and lively mental diversion have been distinctly beneficial.

The advantages of the open car, also, are not to be ignored. The entire freedom of the circulation of the air, even in cold weather, is stimulating and tonic to those vigorous enough to profit by it. Indeed, there are some who claim that they never take cold unless they ride in a closed car. Here, of course, the personal equation must settle the question.

In this connection attention should be called to the use of the "wind-shield." It is said that much greater immunity from respiratory troubles has been observed among professional drivers than was formerly the case. Before the introduction of the wind-shield affections of the ear, the nasal sinuses, and the air passages in general seem to have been much more common than they are now.

The typical expression of countenance of the racing motorist is highly suggestive of mouth-breathing, a habit likely to add much to the risks under discussion.

In estimating its effect upon the air passages, therefore, the fact that the automobile may be either open, protected, or enclosed must be considered. No vehicle is more luxurious or, indeed, more safe for those who are feeble and susceptible to the effect of cold, than a high-grade, well-appointed, modern car. With the windows properly arranged draughts can be prevented, and even the temperature can, to some degree, be controlled. Under such conditions an invalid might travel proper distances without injury and with highly beneficial results. To the same person a long ride in an open or a partly protected car might be attended with discomfort and followed by disaster. In advising a patient, therefore, it is necessary to specify the variety of car he should use and then instruct him as to the precautions necessary in his particular case.

Here, again, the personal equation becomes important. The same currents of air which would invigorate and strengthen a person in robust health might be harmful in conditions of disease of the air passages, as they are recognized to be in disorders of other parts.

In a paper recently presented in Philadelphia by Professor James Tyson on the effect of the use of the automobile upon the heart, Dr. Tyson maintains that many cases of cardiac disease are markedly benefited, the fresh air, moderate exercise, gentle stimulation of the circulation, and mental diversion having an excellent influence.

So, in properly selected cases of respiratory trouble the patients thrive under it, owing to improved oxygenation and nutrition.

To sum up the matter, it would appear that under certain conditions and in certain cases the motorist may expose himself to positive risks. These risks may sometimes be modified or even removed by the use of proper precaution in the selection of a machine and by the exercise of wisdom in using it. Properly used in suitable cases, the automobile may be a valuable therapeutic agent.

These things being true, it is time that knowledge upon the subject had been obtained sufficient to enable us to warn the public of the possibilities of danger and to instruct it as to the best means of protection.

In addition to those precautions of a personal nature which each one using the automobile should observe, the safety and comfort of all would be greatly enhanced:

1. By good country roads, kept in good order.

2. By well-paved city streets, kept free from dirt and from the fine dust which is now allowed to remain after the coarser matters have been removed.

3. By the enforcement of the laws against automobile smoke in our cities as the same laws are enforced in the principal cities of Europe.

Thus would much just criticism of the motor be silenced and many friends be gained to a worthy cause.

All things considered, the final verdict seems decidedly in its favor. The authority of life insur-

ance thus far has not been able to discriminate against it, high medical authority commends it in kindred directions, and common sense, together with experience, seem to sustain it.

1 East Thirty-third Street.

FIRST AID TO THE INSANE AND PSYCHOPATHIC WARDS.*

By ALBERT WARREN FERRIS, A.M., M.D.,

NEW YORK.

PRESIDENT OF NEW YORK STATE COMMISSION IN LUNACY.

Midway between the home and the State hospital there must exist some agency for the care of the mentally disturbed, pending their proper disposition. Some haven must be open for their immediate reception. It should not be the poorhouse and it should never be the jail. It is a blot upon our civilization that the mentally afflicted should be so often treated as if they were paupers or criminals. Hippocrates taught that insanity is due to disease; but sight of this fact was lost in the superstition of the Middle Ages.

Non-restraint of the insane was advocated by Franklin in 1750, and later by Rusk. Yet on the statute books of the State of New York, as late as 1788, was placed "An act for apprehending and punishing disorderly persons," which provided partly as follows: "Persons who by lunacy or otherwise are furiously mad, or are so far disordered in their senses that they may be dangerous to be permitted to go abroad; therefore, be it enacted that it shall be lawful for any two or more justices of the peace to cause such person to be apprehended and kept safely locked up in some secure place and, if such justices shall find it necessary, to be there chained." In 1806 an Act was passed by the State Legislature providing for the erection of additions to the New York Hospital, a general medical hospital, "particularly to provide suitable apartments for maniacs, adapted to the various forms and degrees of insanity." Yet to-day, a hundred years later, we read in the newspapers of "persons charged with insanity," "insane offenders" and "insane prisoners," not sent to hospitals, but locked in jails as if guilty of crime—a distinct retrogression in the conception of the most unfortunate of illnesses

Shall we speak of a man in the delirium of typhoid as a "typhoid offender," or a "prisoner suspected of typhoid"? Since what date has insanity, or other evidence of illness, been considered a crime? By what moral right is an insane person who is charged with no crime considered as or treated as a "prisoner"?

It is a curious survival of barbarism that the evidence of a disordered mind should be considered as "disorderly conduct," and afford opportunity or excuse for arrest by the constable or the policeman. If a policeman encounters a citizen who is shouting in the street, and ascertains that he is suffering severe pain, the officer conducts him to a hospital for treatment. But if he ascertains that the citizen is suffering from mental disorder, the officer takes him to a jail or a lock-up, and later, "charged with insanity," he is taken before a magistrate after being held in "the pen" with criminals of all kinds. Timidity, custom, and indifference are responsible for this inhuman treatment of the sick.

*Read at the Conference of Mayors of Cities of the State of New York, called to discuss Municipal Health Problems, at Schenectady, June 23 and 24, 1910.

The absurd fear of the insane, which has been inculcated by example for generations, occasionally leads the peace officer to use an unwarrantable restraint and a brutal manner toward the poor sufferer, generally weak and confused, often in abject fear.

Violence of the patient is generally in direct proportion to the violence of the captor or keeper. *The California State Journal of Medicine* reports an interesting instance of cowardice in the treatment of an insane person. "A perfectly harmless patient was first tied about with a rope, then rolled in a mattress, and this in turn was carefully roped, something over one hundred feet of rope being used, to tie a harmless sick person," in order to transport him to a hospital.

Magistrates in certain cities in New York State follow the path of least trouble to themselves by sending an insane person to jail to be returned in five days. In some probably recoverable cases death has occurred under these circumstances and following this mistreatment. In an instance that came to my knowledge, an insane man was taken into a magistrate's court by a policeman who had arrested him, and was remanded to jail by the magistrate, to be brought back to court in five days. People who were present say that the man appeared to be insane to everyone but his honor, the magistrate. Nevertheless, he was bundled into a patrol wagon with several criminals, and lodged in jail. At the expiration of five days he was returned to the court, upon the order of the magistrate, and while waiting his turn in "the pen" with several criminals, he died of starvation. In all jail cases positive damage is done to the patient. The early impressions of the mental sufferer are deep and lasting. To be arrested and confined in jail suggests accusation of crime of which the patient knows he is innocent. Hence arise delusions of conspiracy and persecution which the very difficult, if not impossible of eradication. Borderland and undetermined cases, including psychastheniacs with their doubts, dread, fear, inexplicable terror, anguish, or agitation; and also those who suffer from delirium of fever are much damaged by incarceration in cells prepared for criminals in the ordinary jail.

It is not the worthless, useless, idle, or vicious members of society that furnish us with the larger number of insane people. The insane are largely recruited from among the valuable part of the community. In New York over 77 per cent. of the patients received into the State hospitals were engaged in work above the grade of day labor, or were the wives or minor children of men so occupied. In aiding these people the State has given aid to those who most deserve it; to those who in the past were wage-earners and tax-payers.

In 1890 the population of New York State reached 6,171,586 people, of whom 16,006 were insane. In 1890 the estimated population of the State is 8,865,772, of which number 32,650 are known to be insane.

The duration of sane interval in male cases readmitted was: Less than three years in, 64; less than one year in, 35; less than six months in, 24 per cent. Female cases show a slightly longer sane interval because the attacks of those women who suffer from maniac depressive insanity recur at longer intervals than those of male patients.

The length of hospital residence of cases that recover is: Over one year in, 17 per cent.; between

one month and twelve months in, 83 per cent. About 44 per cent. of the cases that recover have suffered less htan one month from their psychoses previously to admission, and nearly 90 per cent. of the recovering cases have suffered from their psychoses less than one year previously to admission.

The length of hospital residence of male cases that die is: Under one month for 14, under three months for 25, under six months for 35, under one year for 48 per cent.

Female patients who die survive somewhat longer than male cases, because of the decreased prevalence of general paresis among women

The patients are not received early enough, or are subjected to devitalizing influences prior to admission. The earliest treatment is often the most important. All disturbing and distressing influences, all confusion and fatiguing agencies should be prohibited. The tenderest nursing is essential from the start, if the full number of possible recoveries is to be reached. Yet in New York State over 500 patients have been brought annually to the State hospitals from jails and lockups. In many cases their condition in the jail has been deplorable and heartrending.

The reports received "showed that in some instances the patient was cared for by a nurse in the jail or elsewhere, or was taken to a hotel for meals, or was found at a boarding house in charge of the authorities, or at the house of an official, some effort being apparently made to provide for his needs and keep him apart from a criminal environment. In regard to one place, the statement is made that the Superintendent of the Poor always hires reliable attendants to care for the patients pending commitment. More frequently, however, the reports showed that the patients were given no special consideration, and were found in unsanitary, uncomfortable, sometimes filthy and vermin-infested cells, not infrequently in company with persons accused of crime, notwithstanding that this is specifically forbidden by law. In one instance the patient was found in the same room with a person accused of being implicated in a murder and developed a delusion that she herself was accused of the crime. In another a patient received a scalp wound by being struck with a pitcher by a prisoner. In still another the report stated that a woman patient was found in a basement cell, without windows, dark and damp, with no toilet facilities and separated only by a slat door from the quarters of a drunken man. Other reports showed that the patients were cared for by prisoners, or were in a common room with drunkards and tramps. Under such circumstances no attempt at medical care and nursing could be expected, and sometimes the most ordinary needs of the patients were neglected. At a jail in one of the larger cities, a woman was found by the nurse in a cell in which she could scarcely sit up, it was so small. 'Three walls were padded with some coarse material, and the fourth, the front, was a grated door. There was no water section or available toilet facilities. The patient was entirely naked and was extremely filthy and dirty.' The village lockups in which the patients were found were sometimes apart from other buildings and little used. The patients in them were sometimes left alone for long periods, and a suicidal attempt and a fire started were among the occurrences reported. Reports of insufficient food, clothing and bedding, og cold, and of inattention to medical treatment and nursing are among those received. In one instance it was stated that the food was bread and water. One man was far advanced in tuberculosis and delirious. Another was very sick, without fire or sufficient clothing, and died two days after reaching the hospital. An epileptic was drenched with a bucket of water whenever he had a fit.

"The worst feature of all in the case of the insane women confined in jails and lockups is the lack of provision for attendance by persons of their own sex. In a large number of instances, the reports indicated that they were left entirely to the care of men. The impropriety and danger of this to both the patients and their cutsodians can scarcely be exaggerated, and accusations of sexual assaults by police officers or jail keepers have been made by some of the women. In this way innocent persons may be exposed to false accusations from which they might have no opportunity to defend themselves. In one instance the nurse found an insane woman entirely nude in her cell, and the only person to attend her was a man who handed her food in at each meal. The detention of women without attendance by persons of their own sex is, to say the least indecent, and one wonders why it is permitted even in the case of those accused of crime."

The remedy is, (1) to take measures that will insure that the responsibility for the earliest care of the mentally affected should be laid upon health officers and not upon poor-law officers, and (2) to provide psychopathic wards or pavilions in connection with general medical hospitals in all cities and large towns.

Superintendents or overseers of the poor should not be in charge of alleged insane persons. Insanity is a form of illness, and these patients should be cared for by health officers in the first instance. When no suitable place has been provided, a health officer will secure room in a boarding house, or with a family, in which the patient may be placed in the care of a nurse till admission to a State hospital can be arranged. No physician will lodge an insane person in jail; but he will provide a safe and comfortable place for temporary accommodation, and proceed with haste to secure medical examination and apply early for commitment to a State hospital. Thus without alarm or brutality, without the demoralization following arrest and jail life, without undue restraint but under the care and quieting influence of a nurse, the patient will be tided over the confusing and distressing period of transfer to a strange place without resulting mental damage. Emphasis will have been placed on illness, and no suggestion of crime will have been made. A bill providing that a health officer and not poor-law officers shall take charge of the alleged insane pending commitment has passed the Legislature, and has been signed by the Governor, becoming Chapter 608 of the Laws of 1910.

The entire avoidance of undermining influences will be secured if psychopathic wards or pavilions, attached to general hospitals, are available. A psychopathic ward is not a room for the detention of vagrants or drunkards. A cage with a bed in it and a keeper outside does not constitute a psychopathic ward or a proper place of detention for the sick.

A psychopathic ward consists of a number of single bedrooms opening upon a corridor or short hall, with abundance of light and ventilation, with ordinary furniture, bedding and equipment, with convenient water sections providing bathing facilities; with nurses (women, with few exceptions) in

uniforms; with plants and flowers supplied with discretion.

The patient should have, if possible, better quarters and more comfort than he has at home. The ministration should be noticeably personal, kind, and encouraging; the food should be appetizing and attractive; medical care and nursing should be as complete as in the case of any other grave form of illness, with a view to saving every ounce of the patient's strength, physical and mental. Separate provision for possible noisy cases should be made in small detached annexes, reached by means of corridors. In all hospitals furnished with psychopathic wards or pavilions there should be a resident physician on call at all times.

The function of the psychopathic ward or pavilion is to provide a proper place for reception and temporary detention of the alleged insane, pending their proper disposition; to receive borderland or undetermined cases for observation and decision; to care for cases of symptomatic delirium and the like. In all instances in which any uncertainty exists the benefit of the doubt should be given to the alcoholic case. A grave psychosis may be masked by alcoholism.

It is an important fact that medical care of the insane should begin before the time when sufficient mental change has occurred to make a commitment possible. The initial care and treatment in the psychopathic ward is therefore of prime importance. But such care is purely initial, not protracted. Without full equipment for the treatment of the insane and without the constant attendance of a resident psychiatrist, protracted care should not be undertaken.

Dangerous statements have been reported to the effect that the insane are of two classes, one class comprising acute and recoverable cases that may be treated in an ordinary general medical hospital and the other class comprising the irrecoverable cases who should be placed under custody in State hospitals. It is very difficult to predict regarding recovery of a patient. Very frequently cases that appear recoverable never emerge; while a few others, after six or even nine unbroken years of mental derangement, make a recovery. The possibility of rapid recovery should not be jeopardized by prolonging general hospital treatment beyond the stage of first aid.

The treatment of the special State hospital, with its exhaustive search of personal or family history, its consultations in meetings of resident medical officers over each case personally and repeatedly presented, its psychoanalysis, its prolonged baths, its therapeutic occupations, its many industries, its classes in calisthenics and folk-dances and its varied entertainments—this should be the treatment afforded the patient at the earliest day possible.

Moreover, in certain States, as in New York, prolonged treatment in the psychopathic ward of a general hospital is unlawful. But all the agencies mentioned are less effectual and less rapidly successful, if neglect or harshness at home, or if arrest and lodgment in jail have preceded the admission of the patient into the special State hospital. The psychopathic ward is a most important link in the chain; a most essential agency for the early protection and conservation of the recently developed or of the recently discovered case of mental impairment.

IS MERCURY A SPECIFIC IN PULMONARY TUBERCULOSIS?*

By WM. N. BEGGS, A.B., M.D.,

DENVER, COLO.

MEDICAL DIRECTOR OF THE EVANGELICAL LUTHERAN SANITARIUM FOR CONSUMPTIVES, EDGEWATER, AND PHYSICIAN TO THE NATIONAL JEWISH HOSPITAL FOR CONSUMPTIVES, DENVER.

In propounding this question, it is fitting to inquire at the beginning, "What have we a right to expect or require of a specific?" In replying to this, it may be said very properly that any remedy or method of treatment, to be a specific in any disease, is one which, when applied *secundum artem*, uniformly results in the recovery of the individuals subject to that disease. By this it is not meant that there may not be any failures of recovery, but these must be comparatively so exceptional as not to vitiate the rule.

From this definition certain other conditions may be deduced as corollaries, of which I shall discuss four. The first of these is that, in an affection characterized by distinct clinical types, the remedy or method of treatment must be applicable with successful results in each of the several clinical types. While we may thus allow for some variation in the success of the employment of the treatment, the variation depending upon the clinical type of the affection, nevertheless, in none of the clinical forms is any considerable lack of success justifiable if the treatment is to be regarded as worthy of the name of "specific."

As applied to tuberculosis, this would mean that when we venture to call any remedy "specific" it must result in cure, when properly employed, not only in tuberculosis of the most varied tissues and organs, but also in the several clinical varieties of tuberculosis in these tissues and organs, if there be such. That is, it is not sufficient that the remedy or method of treatment may be employed successfully in tuberculosis of the skin, bones, joints, lungs, etc., but it must be employed successfully in all the forms of tuberculosis of these organs. It is not possible to lay too much stress upon this feature. Thus, in pulmonary tuberculosis, for example, it is not sufficient that some, or even a large proportion, of the cases of chronic ulcerative (Osler) pulmonary tuberculosis shall improve, perhaps ultimately recover. It is necessary that the same result shall occur in cases of chronic fibroid or chronic parenchymatous pulmonary tuberculosis (in which latter type I have never seen a case of recovery under any method of treatment), although the recovery need not necessarily occur with the same percentage of frequency as in the first named form. Indeed, I will go further, and assert that we have no right to speak of a specific in tuberculosis until the acute forms (the pneumonic, the disseminate, and the miliary) are amenable, as a rule, to treatment.

A second corollary is that such specific treatment shall be successfully applicable in all stages of the affection short of what may be called an essentially "terminal" stage. It must not be restricted in its usefulness to the incipiency of the disease. We do not hesitate to attack a neglected syphilis, for example, although much time may have elapsed since the primary lesion was contracted and the subsequent manifestations have been numerous and varied—I say we do not hesitate to institute treat-

*Read before the Colorado State Medical Association, September 14, 1909.

ment in such cases, with the reasonable expectation that recovery will ensue if the treatment be carried out faithfully and conducted intelligently. Of course, we need not expect that the damage which has been done will be done away with and tissues which have been destroyed will be restored, but the disease itself will be arrested and the patient will recover so far as the defects in the tissues will permit. It is the same way with malaria. To a lesser degree it is true of diphtheria. Here time is a specially important element, on account of the rapid and great destructive degenerative lesions produced by the diphtheritic toxin, which themselves may produce the death of the patient.

In tuberculosis, it is true, there finally comes to be a stage, which we may properly designate as a terminal stage, in which it is probable that the death of the patient would certainly follow at no great length of time as a result of the secondary lesions produced by the specific disease, although themselves not specific, even were it possible for the tuberculous process itself to be absolutely and at once eliminated. This result, as in diphtheria, would occur because of the destructive or degenerative conditions produced by the tuberculotoxins in organs essential to the prolongation of life. However, we should guard ourselves against the error of locating the appearance of this terminal stage too early in the history of the case. To assert a year, or six, or even three months (these periods are used simply for illustration) before the death of a consumptive, that his case is hopeless, is simply to give expression to the meagerness of our present-day therapy and not to the possibilities in his case. The fact that three, or six, or twelve months have been required for a not only tuberculous, but a mixed infection of constantly increasing amount acting upon an individual of constantly diminishing vitality and power of resistance to produce death is evidence that were it possible at such time to eliminate the tuberculous process, the individual might survive indefinitely, the degree in which he is crippled depending upon the extent of the destruction which his tissues and organs have already suffered. Not until such cases can be treated successfully as a rule can we speak properly of having a "specific" against tuberculosis.

A third corollary is that the dosage of such specific may be capable of adaptation according to the degree of severity or rapidity of development of the lesions produced by the disease. It must be possible to adjust the dosage of the remedy to the different relations existing between the varying degrees of virulence and quantity of the infective agency and the variations in the resisting powers of different individuals, or of the same subject at diverse times. In other words, it must be possible to push the remedy in the more virulent cases. This we readily do in syphilis, malaria, and diphtheria. This we must also be able to do as a routine matter in tuberculosis.

The fourth corollary is that there must be no "personal equation" on the part of the physician requisite in the successful use of the remedy or method of treatment. It must be alike successful in the hands of all competent clinicians in that field of therapy. This does not mean that in tuberculosis the method would necessarily be available for use in the hands of the general practitioner, no matter how desirable that would be. To-day the difficulties in the successful management of a case of tuberculosis are vastly greater than exist in a case of syphilis, for example, and it is fitting that the conduct of such cases be carried on by those who have devoted special attention to such subject. With a specific, however, we might expect, even in the hands of those not specially skilled, if the general principles for its administration be once established, better results than may be obtained without a specific by even our ablest phthisiologists.

This corollary also does not preclude entirely the element of personal factor in that always the greater the skill of the physician and the greater his ability to inspire confidence on the part of the patient, the greater will be his success in a given case. In no organic disease more than in tuberculosis, perhaps, does suggestion play a greater rôle in the outcome of the case.

The use of mercury in tuberculosis is no new thing. There is probably no remedy in the whole materia medica which has been applied in as many diverse affections and as carefully proved out in each of them as mercury. Therefore, mercury and tuberculosis have not escaped association in the past, and have not escaped the most careful and exhaustive proving in the past.

I shall make no attempt at a critical study of the literature concerning the use of mercury in tuberculosis, but shall simply make a very few interesting quotations. Good, on page 286, Vol. III, of the fourth American edition of his work on "The Study of Medicine," in five volumes, published in Boston in 1826, speaks as follows: "Consumption, according to Brouillet[1] and many other writers, is identic with scrophula and is only to be cured by tonics, alkalies, corrosive sublimate, or other mercurial alterants employed for the cure of scrophulous affections. According to Cullen, though it has an apparent connection with scrophula, the analogy affords us no assistance in the treatment, and the remedies for the one are of no avail in the other.

"Dr. Rush[2] contemplated it for the most part as an entonic or inflammatory disease, and particularly in its first stage, though it is sometimes accompanied with a hectic, or even a typhous fever. And hence his principal remedies were salivation, or bleeding, which he sometimes prescribed fifteen times in six weeks; emitics, nitre in large doses, a milk and vegetable diet, walking in cold air even during an hæmoptysis, and afterwards severe exercise. . . . This bold practice excited many followers, and was tried with variable success upon a large scale. But a practice of an opposite kind, equally bold, and which soon became equally popular, was proposed at the same time by M. Salvadori, of Trent.[3] Consumption, in the view of this pathologist, is an atonic instead of an entonic disorder from the beginning, a disease of direct debility and not of inflammation; and hence it is only to be cured by an active plan of stimulants and roborants from the first. The patient's diet is to consist of copious meals of meat and wine, and his chief regimen to be that of climbing hills, or precipitous steeps in the morning as quickly as he is able, till he is out of breath and bathed in sweat, and then augmenting the perspiration by placing himself near a large fire. Mr. May,[4] who adopted the same general principle, seems to have postponed the gymnastic part of the process till the symptoms were alleviated." I have made this quotation because of a number of points particularly interesting in connection with several of our most recent and most prominent phthisiological propaganda, as well as because of its relation with the question in hand.

Dr. Rush[5] himself says: "A salivation has lately been prescribed in this disease with success. An accident first suggested its advantages, in the Pennsylvania Hospital, in the year 1800.[6] Since that time it has performed many cures in different parts of the United States. It is to be lamented that in a majority of the cases in which the mercury has been given it has failed of exciting a salivation. Where it affects the mouth it generally succeeds in recent cases, which is more than can be said of any or of all other remedies in this disease. In its hectic state a salivation frequently cures, and even in its typhus and last stage I have more than once prescribed it with success."

It can hardly be urged that Rush has confused pulmonary tuberculosis with pulmonary syphilis when we consider what he has said of the uselessness of mercury in those cases in which salivation cannot be produced, and the success of its employment when salivation occurs. Besides, as Osler[7] says, in speaking of syphilis of the lung: "This is a very rare disease." As a matter of fact, it occurs most frequently in the syphilitic pneumonia of the still-born. He goes further, and says: "Is there a syphilitic phthisis, an ulcerative and destructive disease, due to lues? Personally I have no knowledge of such an affection, either clinically or anatomically, and the cases which I have seen demonstrated do not seem to me to have the characters distinctive enough to separate them from the ordinary tuberculous phthisis."

It may be maintained, however, that while the pulmonary lesion is not syphilitic the individual himself is the subject of an old, hidden syphilitic taint, and that the beneficial effects of the mercury, when such are observed, are due to the eradication of the lues. This would not, indeed, be any more compatible with the peculiar action of mercury as noted by Rush than the indicated possible confusion of the two diseases. In the cases reported by Wright[8] and others at the present day there can be no question but that tuberculosis did exist in the patients, whether with or without an accompanying syphilitic taint. In this connection it is also well to bear in mind the fact that it is generally held that the occurrence of syphilis in a tuberculous patient renders the prognosis as to his tuberculosis much more grave.

In contrast with these views of a hundred and more years ago, Cullen[9] held, at about the same time, that "In scrophula the remedies that are seemingly of most power are seawater and certain mineral waters, but these have generally proved hurtful in the masses of tubercles of the lungs. I have known," he adds, "several instances of mercury very fully employed for certain diseases in persons who were supposed at the time to have tubercles formed, or forming, in their lungs; but though the mercury proved a cure for those other diseases, it was of no service in preventing phthisis, and in some cases seemed to hurry it on."

The conviction of the uselessness and even harmfulness of mercury in tuberculosis gradually prevailed, and for many years has been generally accepted by the medical profession. Indeed, a very noteworthy fact is the unanimity with which it has been ignored in the modern publications on the subject. In recent works on general practice, on materia medica and therapeutics, on diseases of the lungs, or monographs on pulmonary tuberculosis, it is very seldom that we find even mention made of mercury in the treatment of tuberculosis. This is an exceedingly pertinent fact, for it is not to be assumed that during all these years there have been none who have observed experiences such as are mentioned and have not, therefore, given mercury careful and repeated trials.

Only sporadically has an occasionl favorable report been made. Thus in Sajous' Annual for 1889 three papers were mentioned, in 1890, four by three authors, two of them authors of papers mentioned the previous year, and in 1895 one, a total of eight papers by five authors of sufficient importance to be mentioned in the Annual in a period of eight years. None of these had any appreciable effect upon the general opinion and practice of the profession. It was not until the publications of Wright of the remarkable results claimed to have been obtained at the U. S. Naval Hospital at New Fort Lyons that there seemed to be any indication of any inclination to reconsider "the experience of a thousand years summed up by Cullen with the statement, 'Mercury is pernicious in consumption.'"[10]

In the fall of 1906 I was consulted by a couple of patients who had contracted syphilis. One, with the primary lesion, had an incipient pulmonary tuberculosis. The other, in the early secondaries, had two years earlier developed an incipient pulmonary tuberculosis which had been arrested. The pulmonary lesions being only slight, I pushed the mercurial treatment for the lues in both cases, using by preference the protoiodide. Both patients, after the prompt disappearance of the specific lesions for which they consulted me, faithfully continued the treatment, had no further luetic symptoms, and had no trouble with their tuberculosis. Fortified by this experience, I was prepared, when Wright's reports were called to my attention, to give mercury a further trial in what seemed to me to be justifiable cases. I use the word justifiable advisedly. It did not seem to me proper, in view of the overwhelming preponderance of professional opinion that mercury is contraindicated in tuberculosis, to apply it to patients who were already doing well under the recognized methods of treatment, or whose conditions were such that the usual methods of treatment offered hopes of recovery. Many of the cases were dispensary patients, for whom it was not feasible to keep satisfactory records. Many others could not be induced to take the treatment for a time justifying consideration. Of the few which I present, some took the treatment for a very short time only, but their records presented features worthy of mention. In all cases other treatment was given, either coincidently or *ad interim*.

I have made use of several preparations of mercury, *e.g.* blue mass (usually five grains every other night), the protoiodide (gr. $\frac{1}{8}$-$\frac{1}{4}$ after each meal), both by mouth, the succinnimide according to Wright, and the corrosive chloride (gr. 1/32 intravenously). Acting on the principle that whatever effect would be obtained would be due to the mercury rather than the particular salt employed, the use has been varied according to the exigencies of the case. In many cases the succinnimide could not be employed on account of the pain accompanying the injection. Injections have been made without any reference to the appearance of blood after the insertion or withdrawal of the needle—that is, without any reference to the possibility of injection into a vein—and in no case have I noticed evil effect from such injection. Also in no case has there been any abscess formation, although induration is usual.

The following cases were observed in the Evangelical Lutheran Sanitarium:

Case I.—H. C., male, age 30, with negative family history as to tuberculosis and no personal history of venereal disease, came under observation October 6, 1908, having been ill 6 months. Diagnosis: chronic catarrhal pulmonary tuberculosis III,* involving the right lung to the 6th rib anteriorly and posteriorly and to the 8th rib laterally and the left lung to the 6th rib anteriorly, the 8th rib posteriorly, and the 8th rib laterally. Prognosis: unqualifiedly bad. Patient had been failing before taking treatment. The mercurial part of the treatment consisted of blue mass in five-grain doses every other night for six doses (11/7 to 11/20) and the succinnimide, gr. 1/5, six injections in twenty-eight days (12/1 to 12/29) followed by gr. 2/5, one injection (1/2/1909) when salivation appeared. He was again given gr. 1/5 for three injections (1/11/09 to 1/17/09) when salivation again appeared and the treatment was discontinued. He left for home February 4, very much worse.

Case II.—E. B., female, age 21, whose mother, three brothers, and one sister had died of tuberculosis, was admitted August 31, 1908, with negative history as to venereal disease. Diagnosis: chronic catarrhal pulmonary tuberculosis III of three years' standing, complicated with recent hemorrhages. Involvement: right lung to 6th rib anteriorly, laterally, and posteriorly; left lung to 6th rib anteriorly and laterally, 5th rib posteriorly. Prognosis: doubtful. Patient was improving before any mercurial was administered. She was given six doses of blue mass, gr. v (10/27 to 11/6) when she had vague grippal symptoms. Was again given two doses (11/10 and 11/18) when she had headache and digestive disturbances, and the treatment was temporarily stopped. Again she was given twenty doses (1/2 to 2/9) when chilly feelings and coryza ensued (not necessarily referable to the mercury). The mercurial had no perceptible effect on the tuberculosis either during or after treatment.

Case III.—B. G., female, age 18, with family history negative as to tuberculosis and personal history negative as to venereal disease, was admitted October 31, having been ill two years. Diagnosis: chronic catarrhal pulmonary tuberculosis III. Involvement: right lung to 3rd rib anteriorly; left lung to 6th rib anteriorly, 8th rib laterally, and 9th rib posteriorly. She had been improving before administration of mercury. She was given twenty doses of blue mass, gr. v, every other night 1/2 to 2/9) without any apparent influence on the course of the disease.

Case IV.—R. H., female, age 37, whose father died of tuberculosis, and who had had no venereal disease, was admitted July 22, having been ill fourteen years. (She had had a cough more or less regularly for that length of time, but the physical signs were not such as to justify a belief in a tubercular process of any activity of that duration.) Diagnosis: chronic catarrhal pulmonary tuberculosis I. Involvement: right lung to 2nd rib anteriorly and 3rd rib posteriorly. There had been no improvement prior to administration of mercury. For fourteen days she was given protoiodide, gr. 1/8, after each meal, when treatment was interrupted by some slight intercurrent affection. No improvement resulted.

Case V.—A. L., female, age 23, with no tuberculosis in family history and no personal history of any venereal trouble, was admitted August 26, having been ill nine months. Diagnosis: chronic catarrhal pulmonary tuberculosis II. Involvement: left lung to the 6th rib anteriorly, laterally, and posteriorly, progressive. Prognosis: doubtful. Patient began to improve from the beginning. She was given protoiodide, gr. 1/8 after each meal for eleven days (9/20 to 9/30) and again for four days (10/5 to 10/8) when it was stopped. She continued to improve and was discharged much improved and with a much more favorable prognosis. The mercury did not seem to have influenced the course of the disease in any way. Her greatest improvement was under the bacillus emulsion.

Case VI.—H. S., male, age 35, with no history of venereal disease, was admitted July 7, 1907. When I first saw him, August 24, 1908, the diagnosis was chronic interstitial pulmonary tuberculosis III, involving, as shown by physical signs, the right lung to the 6th rib anteriorly, the 10th rib laterally, and the 11th rib posteriorly, and the left lung to the 4th rib anteriorly and laterally and the 6th rib posteriorly. The condition had been practically unchanged, as far as I was capable of judging, until placed on mercury. He was given blue mass, gr. v, every other day for fifteen doses (1/8 to 2/5) and the protoiodide gr. 1/8 after each meal for nine days (3/9 to 3/17) with apparently no change. Recently he seems to have improved somewhat under tuberculinum purum (endotin).

Case VII.—S. B., male, age 36, whose father died of tuberculosis and whose personal history as to venereal disease was negative, was admitted January 5, having been ill about six years. Diagnosis: chronic catarrhal pulmonary tuberculosis III, involving the right lung to the 6th rib anteriorly, the 7th rib laterally, and the 4th rib posteriorly, and the left lung from the 6th to the 11th ribs posteriorly and from the 5th to the 9th ribs laterally. Prognosis: poor. He was placed on blue mass, gr. v, every other night for eighteen doses (1/8 to 2/11) when his gums were touched. There seemed to be slight improvement in his case, but he left the sanitarium and the case could not be followed up.

Case VIII.—G. A., female, age 21, with history negative both as to personal venereal disorders and tuberculosis in the family, entered May 5, 1908, and came under my observation August 24. Diagnosis: chronic catarrhal pulmonary tuberculosis III, of about one year's standing. Involvement: right lung to the 5th rib anteriorly, the 7th rib laterally, and the 8th rib posteriorly, with cavities; left lung to the 4th rib anteriorly and the 3rd rib posteriorly. Prognosis: bad. She had been growing worse more or less continuously. She was given blue mass, gr. v, every other evening for five doses (10/27 to 11/5), again for twelve doses (1/11 to 2/3), again for eight doses (3/4 to 3/18), and finally for seven doses (4/9 to 4/26), and later the protoiodide, gr. 1/8, three times daily, for five days (7/17 to 7/21), digestive disturbances being the cause for the interruptions. She has grown progressively worse, the mercury having seemingly no influence on the course of the disease.

Case IX.—M. K., female, age 39, whose sister died of tuberculosis and whose personal history was negative as to venereal disease, entered November 4, having been ill about four years. Diagnosis: chronic catarrhal pulmonary tuberculosis III, involving the right lung to the 2nd rib anteriorly and to the 4th rib posteriorly, and the left lung to the

*In all of my own cases the classification according to Turban is used to indicate the degree of severity.

6th rib anteriorly and the 10th rib laterally and posteriorly. She had been failing and the prognosis was bad. She was given the protoiodide, gr. ⅛, three times daily for fourteen days (11/7 to 11/20) and blue mass, gr. V, every other night for four doses. Patient grew continuously much worse and left the sanitarium April 12.

Case X.—M. M., female, age 25, with negative history as to family tuberculosis or personal venereal disorder, first came under observation July 14, 1908, and entered the sanitarium January 28, 1909, at that time having been ill about a year. Diagnosis: chronic parenchymatous pulmonary tuberculosis II, involving the right lung to the 3rd rib anteriorly and the 4th rib laterally and posteriorly, the left supraclavicular region also presenting some signs of involvement. Before entering the sanitarium she had evinced signs of slowly progressing disease, during which time she had several times been given short courses of protoiodide. After entering the sanitarium she was given a mild "hepatic" pill containing a small dose of blue mass every other day for seven doses (2/11 to 2/23) and for eight days (2/24 to 3/3) ⅛ grain of the protoiodide three times daily, at the expiration of which time salivation in a mild degree appeared. It seemed to have no effect on the course of the affection.

Case XI.—G. S., male, age 29, with history of no tuberculosis in his family and of having had a chancroid nine years prior, was admitted September 21. According to him he had been ill only two months. Diagnosis: laryngeal tuberculosis and phthisis florida involving the right lung to the 6th rib anteriorly and the 4th rib posteriorly, and the left lung to the 6th rib anteriorly, the 4th rib posteriorly, and the 7th rib laterally. Prognosis: bad. He improved from the beginning and on December 17 the diagnosis of phthisis florida was changed to chronic catarrhal pulmonary tuberculosis II. He had gained seventeen pounds before being placed on mercury. He was given the protoiodide, gr. ⅛, three times daily for thirty-seven days (2/24 to 4/1). His improvement continued, apparently not being affected either way by the mercury.

Case XII.—C. F., male, age 20, whose brother has tuberculosis and who presented no personal history of venereal disease, entered February 23. His illness had begun four years ago. He had practically recovered in Colorado and returned to his former home, where he had a relapse. Diagnosis: chronic catarrhal pulmonary tuberculosis III, involving the entire left lung and the right lung from the 3rd to the 6th ribs anteriorly, from the 8th to the 11th ribs posteriorly, and from the 5th to 9th ribs laterally. Prognosis: essentially bad. He was given the protoiodide, gr. ⅛, three times daily for twenty-five days (2/24 to 3/20). He had been given a dose of the succinnimide, gr. 1/5, on March 10 and had refused to have it again. This was repeated, however, on the 18th and again followed by refusal. From March 22 to April 9 he was given nine doses of the succinnimide, when salivation appeared. He died June 3.

Case XIII.—T. S., male, age 34, with negative family history as to tuberculosis, but a personal history of four attacks of gonorrhea, was admitted January 30, having been ill about four years. Diagnosis: tubercular laryngitis and chronic interstitial pulmonary tuberculosis III, involving the right lung to the 4th rib anteriorly and the 8th rib posteriorly and the left lung to the 3rd rib anteriorly and posteriorly. Prognosis: poor. He continued to lose ground after admittance. He was given sixteen doses of the succinnimide, gr. 1/5, every other day (3/16 to 4/18), when he left the sanitarium slightly improved.

Case XIV.—M. K., female, age 39, whose sister had died of tuberculosis and whose venereal history was negative, was admitted February 28, having been ill two years. Diagnosis: chronic tubuculous pleurisy and chronic catarrhal pulmonary tuberculosis III, involving the right lung to the 5th rib anteriorly and laterally and the 9th rib posteriorly, and the left lung to the 4th rib anteriorly, the 8th rib laterally, and the 11th rib posteriorly, with cavitation. Prognosis: essentially bad. She was failing rapidly. From March 8 to May 10 she was given the succinnimide on alternate days, gr. 1/5 for twenty doses, gr. 3/10 for seven doses, and gr. 2/5 for six doses, when intestinal symptoms appeared. She continued to fail rapidly and left for home June 19.

Case XV.—M. N., male, age 19, with doubtful history of his father having died of tuberculosis and negative personal history as to venereal disease, was admitted February 5, having been ill three years. Diagnosis: chronic catarrhal pulmonary tuberculosis III, involving the left lung to the 4th rib anteriorly and laterally and the 11th rib posteriorly with cavitation, with doubtful involvement of the right lung above the 1st rib anteriorly, and with a tubercular anal fistula. Prognosis: essentially bad. He had been failing rapidly and this continued. He was given the succinnimide, gr. 1/5, on alternate days for twelve doses (3/8 to 4/5) when he returned home, his rapid failure continuing. He was said to have died April 29 of an attack of acute pneumonia.

Case XVI.—A. R., male, age 36, whose father had died of tuberculosis, was admitted March 3, having been ill one year. Diagnosis: chronic interstitial pulmonary tuberculosis III, involving the right lung to the 5th rib anteriorly and laterally and from the 4th to the 11th rib posteriorly and the left lung to the 5th rib anteriorly, the 4th rib laterally, and the 8th rib posteriorly. Prognosis essentially bad. He had been failing rapidly. He was given the succinnimide on alternate days as follows: gr. 1/5 for nineteen doses (3/8 to 4/23), gr. 3/10 for 5 doses (4/30 to 5/8), and gr. 2/5 for two doses (5/10 to 5/14). He died June 5.

Case XVII.—M. D., female, age 18, with negative family history as to tuberculosis and negative personal history as to venereal disease, was admitted February 6, having been ill one year. Diagnosis: chronic catarrhal pulmonary tuberculosis III, involving the right lung to the 6th rib anteriorly, the 5th rib laterally, and the 7th rib posteriorly with cavitation, and the left lung to the 6th rib anteriorly and the 5th rib posteriorly. Prognosis: poor. She was apparently just about holding her own. She was given blue mass, gr. V, every other day for twenty-one doses (3/17 to 4/21) and again for five doses (5/10 to 5/25) without any apparent influence upon the course of the affection.

Case XVIII.—S. H., female, age 25, who has one tuberculous sister and whose venereal history is negative, was admitted February 23, having been ill four years. Diagnosis: tuberculous laryngitis and chronic catarrhal pulmonary tuberculosis III, involving the right lung to the 3rd rib anteriorly and the 5th rib posteriorly, and the left lung to the 6th rib anteriorly, the 9th rib laterally, and the 11th rib posteriorly. She had been failing rapidly.

Prognosis: essentially bad. She was given the succinnimide, gr. 1/5, on alternate days as follows: six doses (3/18 to 3/29) when salivation appeared; three doses (4/17 to 4/22) with an intermission of four days, then one dose (4/27), when salivation again appeared. After an interval she was given a capsule containing one grain of blue mass three times daily for eighten days (7/11 to 7/28), when salivation again appeared. After another interval she was given 1/10 grain of the protoiodide three times daily for twenty doses. The rapidly progressive character of the affection was not affected. She is still under observation.

Case XIX.—M. S., male, age 24, with negative family history as to tuberculosis and negative personal history as to venereal affections, was admitted March 22, having been ill one year. Diagnosis: chronic tuberculous appendicitis, chronic tuberculous pleurisy, and chronic parenchymatous pulmonary tuberculosis involving the right lung to the 2nd rib anteriorly and the 3rd rib posteriorly. Prognosis: poor. He was given blue mass, gr. v, every other day for eighteen days (4/4 to 5/13) without any apparent influence upon his disease.

Case XX.—C. T., male, age 41, family history negative as to tuberculosis, had had gonorrhea in 1895. He was admitted April 20, his illness having, according to his own history, lasted only a year or so, but, according to his brother, having commenced some eleven years ago. Diagnosis: tuberculous laryngitis and chronic interstitial pulmonary tuberculosis III, involving the right lung to the 4th rib anteriorly, the 8th rib laterally, and the 11th rib posteriorly, and the left lung to the 4th rib anteriorly and posteriorly, with marked vicarious emphysema and great displacement of the heart to the right. He had been failing, was very weak, and the prognosis was essentially bad. He was given the succinnimide, gr. 1/5, every other day for eight doses, when he died.

Case XXI.—H. H., female, age 31, with negative family history as to tuberculosis and with personal history of syphilis at about 20, was admitted April 18, having been ill a year. Diagnosis: chronic catarrhal pulmonary tuberculosis III, affecting the left lung to the 6th rib anteriorly, the 8th rib laterally, and the 11th rib posteriorly, and the right lung from the 3rd to the 11th ribs posteriorly. She had been failing rather rapidly and the prognosis was bad. She was given the succinnimide as follows: gr. 1/5 for four doses (4/22 to 4/28), gr. 3/10 for six doses (4/30 to 5/10), gr. 2/5 for six doses (5/14 to 5/28), and gr. 3/5 once (6/1), when salivation appeared. She has been continued on gr. 1/5 for twenty-four doses (6/4 to 9/12) and has shown slight and slow improvement.

Case XXII.—M. M., female, age 45, whose two brothers died of tuberculosis and whose personal history as to venereal disease was negative, was admitted July 10, having been ill fourteen months. Diagnosis: chronic interstitial pulmonary tuberculosis III, involving the right lung to the 3rd rib anteriorly, the 6th rib laterally, and the 5th rib posteriorly, with probable cavitation, and the left lung to the 5th rib anteriorly and posteriorly and the 7th rib laterally, with probable cavitation; laryngeal tuberculosis. Patient had been failing markedly. She was given the protoiodide, gr. 1/8, three times daily for twenty-one days (7/18 to 8/7) and the dose was increased by an extra gr. 1/8 at noon for sixteen days (8/8 to 8/23) when she left the sanitarium. (She has since died.)

Case XXIII.—E. W., male, age 19, having had gonorrhea at 14 and at 15, with negative tuberculous family history, was admitted July 15, having been ill about twenty months. Diagnosis: chronic catarrhal pulmonary tuberculosis III, involving the right lung to the 3rd rib anteriorly and posteriorly, and the left lung to the 6th rib anteriorly, the 9th rib laterally, and the 11th rib posteriorly. Prognosis, poor. He was given the protoiodide, gr. 1/8, three times a day for seven days (7/19 to 7/26) and an added gr. 1/8 at noon for nine days (7/26 to 8/3). Apparently there was no change in the course of the disease.

The following cases have been observed by me at the National Jewish Hospital for Consumptives:

Case XXIV.—D. M., male, age 35, with a history of tuberculosis in his father, one brother, and three sisters, and no personal history of venereal disease, was admitted October 10, 1908, having been ill six years. Diagnosis: tuberculous epididymitis and chronic interstitial pulmonary tuberculosis III, involving the right lung to the 4th rib anteriorly, the 6th rib posteriorly and from the 3rd to 5th ribs laterally, and the left lung from the 4th to the 6th ribs anteriorly. He had been slowly growing worse and the prognosis was poor. He was given the succinnimide, gr. 1/10 every other day for seven doses (3/7 to 3/19) and gr. 3/20 for four doses (3/21 to 3/27), when salivation appeared. Patient has continued to grow worse.

Case XXV.—A. H. E., male, age 29, with a history of tuberculosis in his wife, father, father's sister, and no history of venereal disease, was admitted April 5, 1909, having been ill from two to three years. Diagnosis: chronic catarrhal pulmonary tuberculosis III, involving the right lung to the 3rd rib anteriorly and the 6th rib posteriorly and the left lung to the 5th rib anteriorly and the 2nd rib posteriorly, and an ulcer of the nasal septum (luetic or tubercular). Patient had been doing badly and the prognosis was poor. He was given the succinnimide every other day, gr. 1/5 for eight doses (4/16 to 4/30), gr. 3/10 for eight doses (5/2 to 5/16), and gr. 2/5 for ten doses (5/17 to 6/5) without any influence on the progress of the disease. He died since leaving the hospital.

Case XXVI.—L. K., male, age 21, with negative tuberculous family history and negative venereal personal history, was admitted December 14, having been ill eight to nine months. Diagnosis: otitis media tuberculosa and chronic catarrhal pulmonary tuberculosis III, involving the right lung to the 4th rib anteriorly, the 5th rib posteriorly, and the 7th rib laterally, and the left lung to the 8th rib posteriorly. Prognosis: poor. He was given the succinnimide, gr. 1/5 every other day for nineteen doses (3/19 to 4/24) with apparently slight improvement, but he refused further injections. He was, after a short interval, given the bichloride, gr. 1/32, intravenously, every other day for three doses (5/20 to 5/28) when he again refused. One more dose was given (6/8) and mercurial treatment discontinued because of further refusal. His condition remained about the same.

Case XXVII.—J. S., male, age 26, with negative personal history as to venereal disease and doubtful family history as to tuberculosis, was admitted November 11, having been ill about 2½ years. Diagnosis: chronic catarrhal pulmonary tuberculosis III, involving the right lung to the 2nd rib anteriorly and the 5th rib posteriorly, and the left lung to the 2nd rib anteriorly and the 3rd rib posteriorly, with

cavitation. Prognosis: doubtful. He was given the succinnimide every other day as follows: gr. 1/5 for ten doses (4/2 to 4/20) and gr. 3/10 once (4/22) when he refused to take it. He was given the bichloride gr. 1/32, intravenously, every other day for twenty-seven doses (5/15 to 9/7). The improvement has been very marked.

Case XVIII.—J. G., male, age 30, with negative family history as to tuberculosis and negative personal history as to venereal disease, was admitted March 12. Diagnosis: chronic catarrhal pulmonary tuberculosis I, involving the right lung to the clavicle anteriorly and to the 3rd rib posteriorly, and the left lung to the 3rd rib anteriorly and the 2nd rib posteriorly. He also had a perforated nasal septum which gave rise to the suspicion of lues. Prognosis: fair. He was given the succinnimide, gr. 1/5, every other day for ten doses (3/29 to 4/18) when he refused it. The course of the disease was apparently unaffected.

Case XXIX.—M. B., male, age 22, with negative family history as to tuberculosis and negative personal history as to venereal disease*, was admitted February 19, having been ill six months. Diagnosis: acute disseminate pulmonary tuberculosis III, involving the right lung to the 2nd rib anteriorly and the 6th rib posteriorly, and the left lung to the 5th rib anteriorly and posteriorly. Prognosis: essentially bad. His depression was such that he was kept for a month (2/24 to 3/22) on strychnine sulphate, gr. 1/15, three times daily, and was expected to die during that time. He was given the succinnimide every other day as follows: gr. 1/5 for eighteen doses (3/17 to 4/20), gr. 3/10 for nine doses (4/22 to 5/8), and gr. 2/5 for three doses (5/10 to 5/14), when salivation set in. Patient improved during and after treatment so that a revision of the diagnosis was probably proper. He is now up and about.

Case XXX.—F. S., female, age 25, with negative history as to venereal disease, whose father probably died of tuberculosis, was admitted July 3. Diagnosis: chronic interstitial pulmonary tuberculosis III, involving the right lung to the 2nd rib anteriorly and the 3rd rib posteriorly, with compensatory emphysema, and the left lung to the 4th rib anteriorly and the 11th rib posteriorly with cavitation. The affection was not distinctly advancing prior to being given mercury. She was given the succinnimide, gr. 1/5, every other day for ten doses (4/12 to 4/30) when it was discontinued. Treatment was recommenced after she left the hospital and she was given twenty more injections without any change in her condition.

Through the courtesy of Dr. M. Collins, Superintendent of the National Jewish Hospital for Consumptives, I am enabled to present the following brief data as to other cases treated by other members of the staff of that institution:

Case XXXI.—M. S., male, admitted November 16, having been ill six months. Diagnosis: pulmonary tuberculosis in moderate degree of advancement. Given 30 injections beginning March 19. Condition stationary.

Case XXXII.—R. R., admitted January 7, having been ill 4 years. Diagnosis: advanced pulmonary tuberculosis. Given 24 injections beginning March 3. Died.

*He has very markedly improved. Subsequent closer interrogation revealed a history of an eruption on face and abdomen "like measles," not painful but occasionally itching, for about a year when he was 11 years of age. No other symptoms were remembered.

Case XXXIII.—H. E., admitted June 21, having been ill 3 years. Diagnosis: laryngeal tuberculosis and moderately advanced pulmonary tuberculosis. Given 30 injections beginning March 15. Improved. Was under tuberculin 3 months.

Case XXXIV.—S. L., admitted March 1, having been ill 2 years. Diagnosis: moderately advanced pulmonary tuberculosis. Given 17 injections beginning March 18. Unimproved. Discontinued.

Case XXXV.—F. S., admitted February 12, having been ill 2 years. Diagnosis: moderately advanced pulmonary tuberculosis. Given 30 injections beginning March 3. Slight improvement.

Case XXXVI.—L. G., admitted September 26, having been ill 1 year. Diagnosis: moderately advanced pulmonary tuberculosis. Given 17 injections beginning March 17. Condition stationary.

Case XXXVII.—D. W., admitted December 22, having been ill 1 year. Diagnosis: second stage pulmonary tuberculosis. Given 30 injections beginning March 19. Improved decidedly.

Case XXXVIII.—B. S., admitted January 18, having been ill 1 year. Diagnosis: chronic catarrhal pulmonary tuberculosis, early I. Given 16 injections beginning March 17. Unimproved. Treatment discontinued.

Case XXXIX.—M. S., admitted August 28, having been ill 1 year. Diagnosis: incipient pulmonary tuberculosis. Given 30 injections beginning February 15. Slight improvement.

Case XL.—O. L., admitted August 1, having been ill 5 years. Diagnosis: moderately advanced pulmonary tuberculosis. Given 30 injections beginning February 15. Unimproved.

Case XLI.—E. B., admitted December 30, having been ill 5 months. Diagnosis: incipient pulmonary tuberculosis. Given 45 injections beginning February 11. Unimproved. "Examination of urine after treatment showed heavy traces of albumin. Urine normal before treatment."

Case XLII.—G. C., admitted September 17, having been ill 9 years. Diagnosis: chronic catarrhal pulmonary tuberculosis, second stage. Given 30 injections beginning March 19. Improved. Patient took tuberculin treatment for 2 months.

Case XLIII.—R. S., admitted February 17, having been ill 1 year. Diagnosis: chronic catarrhal pulmonary tuberculosis, second stage. Given 30 injections. Improved.

Case XLIV.—E. J., admitted March 4, having been ill 2 years. Diagnosis: chronic catarrhal pulmonary tuberculosis, third stage. Given 60 injections beginning March 9. Unimproved.

The foregoing fourteen cases were all given the succinnimide intramuscularly. In my own cases salivation was observed in one patient after the ninth injection, in one after the seventh and again after the third, in one after the sixth and again after the fourth, and in one after the seventh and again after the fourth injection.

It may be claimed that these cases are not sufficient to determine the value of any method of treatment in tuberculosis, and that it is not fair to judge of the value of any method by the results in the classes of cases here presented. In reply, I will state that I am not here attempting to establish the value of mercury in tuberculosis. That is a different question from the one heading this paper. These cases, herein reported, have, however, a decided bearing on the question as to whether or not mercury is a specific in tuberculosis, and I would again refer to the corollaries I formulated in the

earlier part of this paper. If mercury is a specific in tuberculosis generally it is a specific in pulmonary tuberculosis, and, conversely, if it is not a specific in pulmonary tuberculosis it certainly is not a specific in any other form of tuberculosis.

Furthermore, I will say that it is certainly not fair to judge of the value of any method of treatment in tuberculosis from the results in incipient cases. This assertion is more than fortified by the favorable results attained in even advanced cases under competent sanitarium management.

The limits of this article would not justify any detailed reference to the opinions of others as shown in recent reports. Suffice it to say that, in this as in most methods of treatment, the personal equation is evidently a very prominent one. A majority of clinicians do not meet with the same results as the originator.

My conclusions may be formulated as follows:

1. Mercury is in no sense of the word a specific in pulmonary tuberculosis. It does not fulfil a single one of the requisite conditions (discussed in the early part of this paper).

2. Mercury is of value in certain cases of pulmonary tuberculosis.

3. With the exception of those cases definitely complicated with syphilis, I have not yet been able to determine in what cases or classes of cases it can be expected to be beneficial. My impression is that it is in those cases in which a luetic taint cannot be excluded with reasonable degree of certainty. It may be of value also in those cases more readily responding to suggestive influence.

4. In a majority of cases the improvement is principally subjective, and there is little or but very slow improvement in the physical signs. In no case have I observed any such specially remarkable clearing up of the physical signs as have been reported by Wright.

5. In those cases in which a luetic taint cannot be definitely or with reasonable probability determined, the improvement is due probably to a simple tonic effect of the mercury, or to its beneficial action on the digestive functions, or to the psychic effect on the patient.

Gangrene of the Lung.—Tomás Hernandez describes two cases of this affection that closely resembled pulmonary tuberculosis during several days. The second case was undoubtedly due to embolism or thrombosis of one of the smaller pulmonary vessels, with subsequent gangrene. Both cases were cured, the cure being almost spontaneous.—*Crónica Médico-Quirúrgica de la Habana.*

HYPERCHLORHYDRIA AND ABDOMINAL AND PELVIC SURGERY.*

By J. H. CARSTENS, M.D.,

DETROIT, MICH.

If we ask ourselves, What is hyperchlorhydria? we will find it a difficult question to answer, because it varies so much in different individuals. One person will complain and be distressed by an excess of acids, while another with 50 per cent. more will have no trouble whatever. Now, it is stated that people differ by nationalities; for instance, the Americans are troubled more, while the Germans, with a far higher percentage of acidity, will complain comparatively little. This might make us believe that perhaps the mode of living, the diet, or climatic conditions have something to do with it. I have often wondered myself if the excessive taking of salt, from which, undoubtedly, hydrochloric acid is derived, would not be a cause of hyperchlorhydria, and still, so far, I have not been able to show it to my own satisfaction. Naturally, I do not see so many cases as the specialists of the diseases of the digestive tract.

Having in the course of years seen many cases disappear, and apparently be cured after an operation, there has gradually been fixed in my mind the idea that many—in fact, I should say most—cases of hyperchlorhydria are due to reflex action, and that especially pathological conditions in the abdominal and pelvic cavity are the exciting cause of this condition. A short report of a few cases might impress this better.

Case I. *Pus Tube and Hyperchlorhydria.*—Mrs. S. A. C., age 25, mother of three children. With the last child she had puerperal sepsis involving the left tube. This continued to trouble her for more than a year. Adhesions would be torn and leakage would take place. She would have a mild attack of pelvic peritonitis, laying her up for a few days, and sometimes two or three weeks. I was called in consultation and advised removal of the tube. Went to Harper Hospital and I operated on her March 25th, 1908. She made a complete recovery, and all her stomach troubles disappeared. This woman was evidently suffering from a mild form of sepsis; it was a mixed infection, streptococcus and colon bacillus. (The former were evidently not virulent, otherwise she would have had more severe attacks.) Although the septic condition may have been the cause of her trouble, I believe it was the adhesion and irritation resulting therefrom that caused her distress.

Case II. *Floating Kidney and Hyperchlorhydria.*—A. J., age 35, mother of four children; suffering from hyperchlorhydria and flatulency. On examination I found the right kidney was loose, coming down as far as the appendicular region. I considered that at the bottom of her troubles. I fixed the kidney as near to its normal position as possible March 28, 1908, and had the pleasure of seeing all her symptoms disappear. It is hardly necessary to say that this loose kidney was caused by a fall, and that she was not suffering from general abdominal ptosis. In the latter case I do not operate on the kidney as a rule, because it does no good; it is only one factor in the general relaxed condition of the abdominal viscera.

Case III. *Appendicitis and Hyperchlorhydria.*—

*Read at the meeting of the American Gastro-Enterological Association, June 6, 1910.

Mrs. G. L., aged 31, widow. Has to struggle along taking care of her children. For several years had several slight attacks of appendicular colic. As they were becoming more severe, I was consulted and advised removal of the appendix. She seemed to worry more about her stomach trouble than the appendix, but I thought both might be relieved by an operation. Went to Harper Hospital May 27, 1909, and I removed the appendix, which was adherent and club-shaped. Before she left the hospital she was already much improved, and when I heard from her, six months afterwards, she was in good health. I have seen a good many cases of so-called appendicular catarrh causing various kinds of digestive disturbances and emaciation, that have been promptly relieved by the removal of the appendix.

Case IV. *Gallstones and Hyperchlorhydria.*—Mrs. W. P., age 53. Menopause, no pelvic trouble, but suffering from attacks of biliary colic every little while; and the most excessive acidity of the stomach. I operated on her August 27, 1908, removing eight large stones. All her symptoms disappeared and she is now the picture of health. In my experience, gallstones are frequently—I might say, are the most frequent—causes of hyperacidity, and I most carefully examine such cases and try to make a diagnosis of gallstones.

Case V. *Vaginal Hysterectomy and Hyperchlorhydria.*—Mrs. A. G., age 38, mother of one child 17 years old. Has had chronic pelvic inflammation and retroversion for years with procedentia —the latter was increasing rapidly. With everything adherent and bound down, I decided the removal of the uterus, tubes, and ovaries per vagina would be the least dangerous operation, and at the same time offer the best chance for a complete cure. This was performed December 1, 1909. It is wonderful how rapidly she improved in health. The stomach troubles disappeared, and she says she feels better than she has for fifteen years.

Case VI. *Dysmenorrhea and Hyperchlorhydria.* —Miss C. B., age 20, has been a terrible sufferer from painful menstruation ever since it started, five years ago. She would be laid up one and two days every month. The lady for whom she worked brought her to me. I found the uterus anteflexed, cervix small and stenosed. I inserted a stem pessary January 20, 1910, left it in four months. Absolutely complete relief of the dysmenorrhea. She called on me the other day, as she was going to leave the city, to thank me, and called my attention to the wonderful change in her stomach. All the hyperchlorhydria had disappeared, she could eat all kinds of food, and had gained in weight. This was a new experience to me, and I therefore put this case in the list, although the operation was not an abdominal one.

Case VII. *Gallstones, Appendicitis, and Hyperchlorhydria.*—Mrs. J. R. P., age 57, has suffered from hyperchlorhydria for many years. Had consulted many specialists, been to Carlsbad and various other resorts of this kind, without much benefit. For about six years symptoms of gallstones developed; she would have slight attacks of colic, and it is only a year or two that a correct diagnosis was made. During this time also pain developed in the region of the appendix, and it was a question whether the appendix or the gallstones caused her trouble. I suggested that an operation be made and the appendix removed, as well as the gallstones. She was operated upon April 28, 1910. Six large stones half an inch in diameter, faceted, were removed, and the gall bladder drained. The appendix was found thick and hypertrophied, and back of the cecum, firmly adherent, and was removed with great difficulty. However, she made an uninterrupted recovery and returned home in three weeks. She says she feels like a new woman. All her stomach and other symptoms have disappeared and she looks 20 years younger.

Cases of this kind I could multiply many fold, but have just selected typical cases of each variety of trouble. What do they show? Adhesions in the peritoneum which interfere with peristalsis, or with movements in certain positions of the body they pull and tug on certain organs, and thus irritate, and as all these are intimately associated with the solar plexus, it seems to me that irritation of the solar plexus, no matter how produced, will cause many cases of hyperchlorhydria. In other words, I believe that hyperchlorhydria, in the vast majority of cases, is due to reflex action and irritation of the sympathetic nervous system.

You will notice I say nothing about gastric or duodenal ulcers. I have had little experience in those, but believe that they also, in some cases, cause hyperchlorhydria by producing inflammatory and congested conditions of the mucous membrane directly, hence hypersecretions of all kinds. Many a time I have given my friends who are specialists in gastroenterology a jocose dig, saying that they treated cases for us without knowing what was at the bottom of the trouble. Of course, I do the same thing, and so does every physician. It is absolutely impossible always to find out the origin of the trouble.

What I have stated, and here want to repeat, is that cases of hyperchlorhydria that are not relieved by the ordinary treatment in the course of a reasonable time, should be subjected to an exploratory abdominal section, so that an exact diagnosis can be made. Sometimes the operation may fail to reveal the trouble, but I think in the vast majority of cases it will be found that there are adhesions of gall bladder, stomach, intestines, appendix, and pelvic organs that by reflex action produce that peculiar condition that we call hyperchlorhydria. Operations indiscriminately made use of I discourage as much as any of you, but I think that the stomach specialist should make more frequent use of abdominal surgery, which is now so free from danger, in obscure troubles of the digestive tract.

In conclusion I would say:

1. Hyperchlorhydria varies in different individuals.
2. Hyperchlorhydria is a symptom, not a disease.
3. Hyperchlorhydria is most frequently caused by reflex action.
4. Hyperchlorhydria is probably due to irritation of the sympathetic nervous system.
5. Persistent hyperchlorhydria should be cleared up by an exploratory abdominal section.

620 Woodward Avenue.

IS KOCH'S BACILLUS THE CAUSE OF CANCER?

By THOS. G. McCONKEY, M.D.,

SAN FRANCISCO, CAL.

In a previous paper (*New York Medical Journal*, Dec. 19, 1908) I presented evidence sufficiently conclusive, I believed, to condemn the tubercle bacillus as the cause of malignant growths. This evidence was derived from a study of tuberculosis and can-

cer in their clinical and pathological aspects. There is such an embarassment of riches in the way of evidence pointing like finger boards to the truth of this theory of cancer, that the necessity for brevity made the article little more than an outline. Whether my selection from the wealth of evidence was not the most judicious or whether the presentation of this evidence was at fault or whether for some other reason, the paper with a few exceptions has apparently attracted no attention. Feeling sure that a hypothesis that furnishes an explanation of more of the unsolved problems of cancer than any yet suggested and against which I, at least, cannot find a single contradictory fact after more than two years of investigation, only lacks verification experimentally in order to be accepted, I am constrained to present additional reasons for my belief and also offer some suggestions which will, I hope, hasten this verification.

The fundamental conception in this hypothesis is that the tubercle bacillus, by reason of its well-known effect of causing normal tissue cells to take on the habit of proliferation, supplies the missing factor in the etiology of cancer. In the young or robust this cell proliferation is normally checked by a defensive reaction on the part of the body, and a "tubercle" is formed by the encapsulation of the minute colony of proliferating cells. But if this cell proliferation is set up in one in whom the defensive reaction is delayed or inadequate, the encapsulation does not take place and the proliferation continues with the result of its becoming a malignant growth.

Bashford says "what is understood by the malignancy of a tumor is but a manifestation of the power of growth: a conclusion to which Apolant and Ehrlich have recently given confirmation." Adami says "as the consequence of the primary stimulus there develops a colony of cells, all tending to proliferate. Thus is acquired the 'habit of growth,' the factor common to all tumors. It is believed that whatever the origin of the tumor proper, however it is started, what makes the tumor is the assumption by the primary cells of that tumor of the habit of growth in place of the habit of work." There we have the cancer problem concisely stated by the best authorities of to-day. Is not the tubercle bacillus as a "primary stimulus" the agency above all others capable of developing "a colony of cells all tending to proliferate"? Permit me to recall some text-book facts in the histogenesis of the tubercle. Baumgarten found that the fixed cells of the tissue took a much more prominent part in the formation of tubercles than had generally been supposed. He found that the first changes in the tissue were coincident with the appearance of the bacilli. Under the influence of these the fixed cells, whether gland cells, endothelial cells of blood-vessels or lymphatics, or connective tissue cells, became enlarged, pale, and finely granular with a tendency to proliferate. McCallum (Modern Medicine) speaking of this tendency to proliferate says it is "a proliferation analagous to the healing process, but in this instance quite disproportionately intense when compared to the injury done to the tissues. Apparently there is a continuous injury or irritation which maintains the proliferation." I wish to emphasize the fact that the nucleus of the tubercle is made up of a "colony of cells, all tending to proliferate." The nucleus of every tubercle possesses in potentiality the requirements for a malignant growth. But this colony of growing cells is checked in its further growth by encapsulation. The elements going to the formation of the capsule are apparently derived from the lymph rather than the blood, for they consist of a fibrillar network of coagulated lymph in which are enmeshed lymph cells. McCallum, in order to explain the continued tendency to proliferate, assumes a hypothetical "continuous injury or irritation." This is unnecessary; the cells, in continuing to multiply as long as nourishment is furnished them, are simply obeying the tendency to proliferate inherited from the mother cell. Inasmuch as the nucleus controls the cell in the matter of reproducing itself as well as functioning, the tendency to reproduction resulting from the presence of the bacillus must lie in its effect upon the nucleus. The facts that the bacilli are found "lying near the nucleus" and that nuclein containing nitrogen and phosphorus in assimilable form is the natural pabulum of the bacilli point to the same conclusion. But, whatever the *modus operandi*, it is an accepted fact that the tubercle bacillus has the property of causing normal fixed tissue cells to give origin to a colony of cells with the tendency to proliferate. Place this fact in juxtaposition with Adami's concise statement of the cancer problem given above and note how completely the tubercle bacillus fulfills the requirements of his "primary stimulus." If evidence of the presence or previous presence of the tubercle bacillus is found in such a large percentage of bodies at autopsy, regardless of the cause of death (98 per cent, according to Nageli), and we have a chronic disease like cancer with no known cause, it is certainly wise to suspect the tubercle bacillus as this cause. This should especially be true if clinically the two present numerous analogies and contrasts which are not accounted for by any other theory, but which analogies and contrasts are not only consistent with this theory, but satisfactorily explained by it. For example, take the contrast in the matter of age incidence in tuberculosis and cancer and note how it accounts for the fact that one is essentially a disease of the first half of life, while the other is essentially a disease of the last half of life. Or take another contrast: mortality from cancer is increasing while mortality from tuberculosis is decreasing. This theory predicates just this state of affairs. In the State of New York the number of deaths from pulmonary tuberculosis for 1909 was 13,948 as against 14,316 for the year 1908, while the cancer mortality was 7,034 for 1909 against 6,534 for 1908. In other words the decrease from phthisis was 368, but the increase from cancer was 500. Numerous theories have been suggested to account for the increase of cancer, but none of them stand the test. If this theory of the etiology of cancer had nothing else to recommend it than that it does explain satisfactorily the increase in the disease, this alone should compel respect for it.

It is evident that the larger the colony of proliferating cells becomes the more difficult it will be to encapsulate it and convert it into a quiescent tubercle. If this cell proliferation is set up in one in whom the defensive reaction is delayed or inadequate, encapsulation is lacking and the proliferation continues, and a malignant growth results. The effort to encapsulate these infiltrating cells is still kept up, but is abortive and only serves to furnish nutrition to these proliferating cells, which are devoid of any altruistic property, but are endowed with the power of reproduction. It happens that lymph is the normal food of cells, and the laudable

but futile effort to encapsulate them brings this food to the colony, especially to the outer concentric layers. The amount of this food supply would depend upon the efficiency of the lymphatic system. Herein lies the explanation of the well-known fact that the growth of cancer in the young is more rapid than in the old. Bashford says "the influence of age is active in relation to the origin of cancer, but not in relation to its continuation: for cancer can be propagated almost better in young than in old animals." Speaking of transmitted cancer, Bashford says "the tissues of the new hosts do not acquire any cancerous properties: they merely react to the cancer cells and supply them with nourishment." The animal body has learned to protect itself against the growing colony of cells by encapsulating it and converting it into a harmless tubercle, harmless for the time as contrasted with an infiltrating malignant growth, which it would otherwise become without such encapsulation. That this encapsulation is accomplished by the lymph is proved by the experiment of producing tubercles in the cornea, a tissue devoid of blood vessels. We know that, in later adult life and in advanced life, the lymphatic glands are usually somewhat atrophied. This corresponds to the age incidence of malignant growths. Is it only a coincidence?

In proportion as we study infection by Koch's bacillus from the point of view of the biologist will a clear comprehension be had, not only of the phase called "tuberculosis" and "scrofula," but the third phase which manifests itself as "cancer." While there may be difference of opinion regarding the mode of entrance of the bacillus into the body, there is unanimity regarding its mode of exit. Its continuance as a species clearly depends upon the fact that it is expelled from the lungs in enormous numbers with the prodigality nature commonly employs in order to insure the continuance of the species. The normal habitat in the body of the tubercle bacillus is the lungs, in which it finds suitable conditions for its multiplication and its natural exit. When found in other organs or tissues than the lungs or lymph glands, it is accidental or aberrant, for tuberculosis of such vital tissues as the meninges of the brain, for example, has no survival value for the parasite; indeed in encompassing the death of its host, it thwarts the interests of the parasite, for the longer the host lives and disseminates the germinating matter of the parasite, the better it is for the parasite as a species. We must get away from the idea that the parasite is always trying to kill its host. In a condition of perfect parasitism the host is not even discommoded by the parasite. The very existence of parasitism means that through the operation of the laws of heredity and adaptation there has evolved a *modus vivendi* that permits both host and parasite to live in this relation. Tubercle formation is neither the product of the tubercle bacillus alone, nor of the host alone. It is the resultant of the interaction of both these organisms, and it contributes, we may be sure, to the continuation of both as species. Let us try to understand how this specific formation, the tubercle, subserves the interest of both host and parasite. Koch, in his original paper, announcing his discovery characterized tuberculosis as "exquisitely infectious." Like every other highly infectious disease we should expect it to be a disease of childhood so far as "catching it" is concerned. Theobald Smith says "tubercle bacilli do not differ materially from other infectious agents who find their easiest prey among the young."

In *Progressive Medicine* for March, 1908, one may read: "In older children and in adults, a reaction is obtained in a very high percentage of the cases, as would be expected from the great frequency of tuberculosis at this period (97 per cent, according to Burckhardt)." Hamburger of Germany maintains that tuberculosis is a children's disease in the ordinary acceptation of the term. Just as nearly every man has had measles once during his life and usually during childhood, so almost every man has acquired tuberculosis once during his life and in most cases during childhood. In researches carried on with Dr. Monti, he has found a frequency of tuberculosis of over 90 per cent at the age of puberty. Startling as these findings are we have no reason to doubt them, for they have been confirmed by autopsy statistics. It is evident that not over ten per cent of those infected are destined to die of tuberculosis of the lungs, and these deaths will occur mainly between the age of fifteen and forty-five. If these 90 per cent and more of infected children succumbed to pulmonary tuberculosis there would soon be no human race. Fortunately for the human race, and also for the bacillus as a species, the bacilli are usually delayed in the lymph glands, or, if reaching the lungs, are tied up there in tubercles. The bacilli are thus rendered latent until the child has reached the age for having children of its own. "The general rule in cases of children is that the lymph nodes are primarily attacked and that the lungs are infected from them" (Harbitz, quoted by Theobald Smith). Tubercle formation, therefore, has survival value for the parasite by bringing about a latent condition, and thus favoring its transmission to the next generation. The period from 15 to 45 years of age is the period of greatest morbidity as well as mortality from tuberculosis of the lungs, and this coincides exactly with the period when children are being born to parents and are in most intimate contact with them.

Scrofula was considered a separate disease entity until proved to be a phase of tuberculous infection. The body is abundantly supplied with lymphatic glands, which nature selects as least vital and best adapted to detain the bacilli whose ultimate destination is the lungs, until the infected child itself has reached the age for children of its own. Speaking generally, scrofula is the usual manifestation of infection with Koch's bacillus up to the age of puberty: pulmonary tuberculosis from puberty to the forty-fifth year; and cancer after the forty-fifth year. In youth and early adult life the lymph glands are pink due to functional activity and freedom from foreign matter, while in later adult life they are "somewhat atrophied and darker in color." This would imply a decreased efficiency so that the prompt and vigorous reaction causing the formation of the tubercle does not take place, and the colony of proliferating cells continues to grow. An effort to surround these multiplying cells and encapsulate them does occur, but this is now futile and the lymph and lymph cells, sent by the body for this purpose as a protective reaction, unfortunately become the food for the continued growth of these infiltrating cells. Councilman says "the characteristic of cancerous growths is that they are capable of attracting to themselves a supply of nourishment at the expense of the surrounding tissue." This seeming power to "attract" nourishment is nothing but the protective reaction against these invading and infiltrating cells with the purpose of hedging them in. Beaston says "Whatever the

origin of the first cell or cells that start a carcinoma, the relation of their numerous offspring to the tissues invaded is that of a parasite in the sense that they get their nourishment from them."

There is no mystery about cancer if we will only open our eyes and see. What is needed is not so much new facts as the correct interpretation of well-known facts. The experimental production of malignant growths by means of the tubercle bacillus is certain to be accomplished soon, and in order to hasten this event I am going to offer some suggestions to the laboratory workers. I am not a laboratory worker myself but a clinician and student of laboratory findings. Theobald Smith, to whom I am much indebted for first directing my attention to the importance of the study of "tuberculosis" from the standpoint of the biologist, has said: "Experimental medicine and clinical medicine must work hand in hand, with the closest cooperation, if one does not wish to disappear in pitfalls unknown to the other."

The experimental verification of this theory will be accomplished by imitating the natural conditions as closely as possible. A species of animal which is not very susceptible to tuberculosis of the lungs should be selected. This would rule out at once guinea-pigs and rabbits, and would point to the canine species. Furthermore spontaneous cancers have been found in dogs but not in rabbits. I cannot speak regarding guinea-pigs, but I should scarcely expect that they would differ from rabbits in this respect. The individual dog should be preferably an old dog and emaciated rather than fat. A very few bacilli should be injected into the general circulation through a vein of the ear. The aim now should be to cause one or more of these bacilli to find lodgement in a fixed cell or cells of tissue which is poorly supplied with lymph. Organs undergoing atrophy from cessation of function, as the mammary gland and the uterus, furnish such tissue with diminished lymph supply. In the absence or inaccessibility of such organs, particular spots should be selected in which the lymph current is known to be away from rather than toward, such as the tip or edge of the tongue or ear, rather than the body or center, or the cervix, rather than the fundus of the uterus. This would also suggest the nipple, rather than the mammary gland. It has been shown experimentally that resected or sected lymphatic trunks can never be traced across scar tissue and their walls are found in a thickened and obliterated condition. This fact could be taken advantage of by making a cut around the selected area and permitting it to heal, the scare effectually obstructing the flow of lymph to the enclosed area. Very slight pressure serves to stop the slow lymph current without stopping the blood current. It is this pressure rather than "irritation" that explains the predisposing effect of gallstones to cancer, or the pipe in epithelioma of the lower lip, likewise the cud in the mouth of the betel nut chewer. The practical application of these suggestions can be trusted to the laboratories. I will only add that an old mother dog with pendant mammary glands and nipples, upon which a gentle pressure can be applied by an elastic bandage or harness, appears to me an especially promising animal.

The natural question occurs: How does a malignant growth as a manifestation of tuberculous infection subserve either the interest of host or parasite? I do not think that it has any survival value for either and in this is like tuberculous meningitis, which is purely accidental or aberrant. The tubercle bacilli would presumably retain their property of setting up cell proliferation indefinitely, but the other factor in the formation of the tubercle, the reaction of the host, is lacking. An ineffectual reaction does occur, but this only furnishes the needed nourishment to the growing colony. When this theory is verified it will appear incomprehensible that it remained so long undiscovered. Speaking of Harvey's teacher, Dr. Osler said: "How Fabricius, a man who did such work—how a teacher of such wide learning and such remarkable powers of observation, could have been so blinded as to overlook the truth which was tumbling out, so to speak, at his feet, is to us incomprehensible. But his eyes were sealed, and to him, as to his great predecessors in the chair (at Padua) clear vision was denied." We of to-day are, of course, just as blind to obvious truth as were Harvey's predecessors and contemporaries, but we pride ourselves on being more receptive to new truth.

OBSERVATIONS ON THE PATHOLOGY OF MULTIPLE ADENOMATA OF THE RECTUM.*

By JEROME M. LYNCH, M.D.,

NEW YORK.

ADJUNCT-PROFESSOR OF RECTAL DISEASES, NEW YORK POLYCLINIC.

In presenting the results of my recorded observations on two interesting cases of rectal, multiple adenomata, it is my hope that others may be sufficiently interested to record and report their own cases; and that our admittedly scanty information on the pathology of this unusual and serious diseased condition may be materially added to.

It is my impression that approximately 46 per cent. of recorded cases of these adenomata terminate in cancer and that the ultimate results are usually fatal; yet the scientific investigation of these tumors has been so comparatively rare and isolated that our actual knowledge of the causes and conditions is lamentably meagre. It may be said that its pathology is not at all established.

Location.—According to Lichtenstein the relative number of instances of these tumors in the different parts of the intestinal tract is indicated in the following arrangement (the most frequent site of occurrence being in the rectum): Rectum, ileum, colon, ileocecal valve and duodenum.

Malignant degeneration naturally affects the parts named in about the same comparative order of distribution, with the exception of the ileum; this latter being less exposed to insult by reason of the fluid condition of the feces in this region.

It may be noted that these tumors usually manifest themselves in patients of between 25 and 35 years of age, and the malignant degeneration consequently occurs much earlier than cancer usually occurs.

About 50 per cent. of the cases collected from the literature were under 35 years of age. A brief summary of the current theories on the origin of these tumors and their transition into carcinoma may be of interest. Hauser, the chief representative of one view, believes that the polypoid excrescences originate through a primary proliferation of the mucous glands leading to a degeneration of the glandular epithelia, expressed by a loss of physio-

*Read before the American Proctologic Society, at St. Louis, Mo., June 7, 1910.

logic function and increased affinity for the stain, differing in no way from cancerous degeneration of the epithelium. The growth is not unlimited, however, and the degeneration is assumedly likely to occur at a time when the form of the glands is not yet modified in any way and no changes of any kind are present in the connective tissue. Meyer believes that the early stage of the process should be sought in the connective tissue. He regards the entire process of epithelial change as secondary, and holds that the phenomenon of multiple polypoid formation can be explained only by a congenital tissue malformation of the bowel wall. This is the primary factor and involves the mucosa and submucosa, and the visible epithelial change should be interpreted as the result of inflammatory stimulus rather than in the sense of a loss or cessation of the physiologic function.

Lebert and Schwab likewise regard the connective tissue proliferation as primary, but they believe that this is determined by chronic irritation. In the cases examined by them the glandular tissue was found to participate in no way in the polypoid formation, the process starting directly from a new formation of vessels, for which an inflammatory process causing a permanent irritation of the mucosa is held responsible.

Pathological Findings.—Several tumors were removed from each case from the smallest size to the largest. The smaller tumors (that is those that had recently sprung up) were shown to be composed mostly of granulation-tissue which showed numerous small blood vessels and interstitial fibroblasts. The entire structure is infiltrated by an acute exudate of leucocytes and serum, showing an acute inflammatory process. At the base of the polyp are a few slightly hypertrophied but rather typical glands. The surface epithelium over the polyp shows complete desquamation. The tumor appears to be composed almost entirely of an inflammatory granulation tissue.

Diagnosis.—The section through the large polyps taken from the same individual as the above but at an advanced stage shows a growth composed of adenomatous glandular proliferation. There is a narrow peripheral margin in some places about the growth which shows granulation tissue. The greater part of the growth about the periphery is composed of simple adenomatous glandular proliferation. Throughout the polyp there is an exudate of serum and leucocytes, the latter showing a predominating number of eosinophiles. There is complete desquamation of the superficial epithelium. Some of the glands in the adenoma appear typical but the greater number are very much larger than those of the rectal mucosa and are in a condition of marked hypersecretion.

These two reports are selected as being typical of what was found in the small and in the well developed tumors, and I believe go to show an inflammatory starting point, with a later proliferation of glandular tissue, which corresponds, to a great extent, with the findings of Lebert and Schwab. Much more might have been learned had we been fortunate enough to have secured a postmortem on the patient who died, as I am confident some of the tumors in the upper part of the sigmoid would have shown carcinomatous degeneration. Then, again, a section through a growth down into the bowel might have thrown some further light on the subject. However, I hope to continue this investigation when another opportunity offers. Granting, then, that these tumors are of inflammatory origin, the next question that interests us is, Why do those tumors undergo carcinomatous degeneration? Adami's explanation seems plausible. Adami says in substance:

We now recognize definitely among the blastomas some change in the biological properties of particular cells as an essential for neoplasm proper. We recognize that there must be an inherent and permanent alteration in the properties of the cells that are to constitute the neoplasm. Biologists, however, are coming to see that *mutations in animals and plants are not chance occurrences.*

It must be recognized that alterations in environment favor frequency of mutation.

All recognize change in cell properties, but, so far, no one has laid down a rule or principle as to the underlying influence or stimulus which brings about the change.

From study of the life history of tumors of differing type this principle seems to be that change is consequent upon long continuance in any state in which, through cell displacement, vegetable activity is possible, while functional activity is inhibited. It may be now a grade of chronic inflammation with accompanying arrests of function without arrest of nutrition, a state which may be of either mechanical or microbic origin.

At another time it may be a senescent exhaustion of the functional capacities of the cell that favors the assumption by that cell of vegetation to the exclusion of functional activities, an assumption accompanied by alteration in the histological character of the cell. The more we study the life histories of the different orders of tumors, the more we investigate the circumstances associated with the development of different examples of one particular order of tumor (such as the cancerous), the more it is impressed upon us that there is no specific causative agent, and that a multiplicity of agents induces a particular grade of cell reaction. All these causes may lead to a modification in the cell properties, a modification that is not transient but permanent and conveyed to subsequent cell generations.

Case I. Mrs. L. R., 39 years, married and the mother of several children.

She was perfectly well up to four years ago, when she had an attack of diarrhea, which was ushered in by bearing-down pain in the rectum with an intense desire to move the bowels—so much so that she would sit in the toilet for long periods, straining, without getting much relief. At times the desire to move the bowels became so imperative that she would not have time to reach the toilet and would soil her clothes. At first she had fairly good movements, mixed with blood and mucus. Later, she passed large quantities of blood mixed with mucus. This condition lasted for about a month and gradually abated. Ever since that time her bowels have been irregular. At times she would be comfortable, but from time to time would suffer acute exacerbation.

She went along in this way for two years before seeking medical aid, and was then treated by different physicians, who did not examine her but used drugs, with indifferent success.

One year ago she was examined at one of the hospitals in New York and was told she had tumors and an operation was advised and consented to. In November, 1909, several tumors were removed by cautery, but she suffered such intense pain after the

operation that she did not return for further treatment, considering herself benefited by the operation, but dreading repetition of the pain. In February, 1910, she drifted into my clinic at St. Bartholomew's. She had then lost considerable weight, was very anemic and poorly nourished.

The rectum and lower sigmoid were found studded with polypoid sessile growths varying in size from that of grape seed to that of a cherry. The examination also disclosed numerous ulcers of the mucous membrane, their size varying from that of a pin head to one-half an inch in diameter. The remainder of the membrane was granular, bled easily, and was covered with mucus, blood, and pus. The upper portion of the sigmoid was fairly healthy.

The treatment advised consisted of an enema of cold, normal salt solution morning and evening, with an occasional additional injection of 25 per cent. solution of aqueous fl. ext. of krameria.

She was kept under observation, and still visits the clinic twice each week, the improvement being marked after the first treatment, which occasioned the patient so little inconvenience that she has gladly followed the prescribed course and is regular in reporting. The improvement has been steady until, at the present time, all ulcerations have disappeared, and the growths have been gradually absorbed until but one remains.

Several polypi were removed for pathological examination, the results of which have been given in the condensed pathological report of these cases.

Case II. Miss S., age 35, dressmaker. Father died of some bowel trouble. Elder sister suffers from diarrhea, with passages of blood and mucus, and was examined at one of the hospitals and told that she had polypoid growth of the rectum. The patient related a history of chronic constipation from childhood, but had been fairly healthy up to about five months before I saw her. At that time she began to suffer from severe attacks of diarrhoea with passages of blood and mucus, these attacks continuing up to the time that I was consulted. Up to a month prior to that time she absolutely refused to be treated by a physician, until her family finally persuaded her to seek medical aid, and she consulted their family physician, Dr. White, who advised immediate removal to the hospital, which she absolutely refused. Four weeks later she consented to enter the Polyclinic, and my services were asked by Dr. White. When I first saw her she was so emaciated that it seemed to me improbable that she could live more than a few days.

Proctoscopic examination showed that the rectum and sigmoid were studded with growths of all sizes and the mucous membrane ulcerated and covered with bloody pus.

I at first ordered astringent injections, but found that they could be given only with difficulty and that they were retained but a short time. The leaky condition of the bowels was such that partial operations constantly occurred at intervals as short as five or ten minutes and the patient was necessarily upon a bed-pan all of the time. I sugested operation for an artificial anus above the growth as the only hope of saving her life. At the same time I told her people that her survival of the operation was doubtful; but it was nevertheless agreed to by relatives and patient as her only possible chance.

An incision was made to left of rectus muscle above the umbilicus and the bowel explored rapidly. Palpation established the fact that the sigmoid and a portion of the descending colon were filled with growths. As we had to twice suspend operation to revive the patient, further exploration was not deemed wise. We therefore brought out a portion of the transverse colon and rapidly closed the wound—the entire operation lasting only ten minutes, including the time required for resuscitation.

The bowel was opened in forty-eight hours after the operation and from that time on the patient was artificially fed by passing tube through transverse colon, as she refused to take nourishment per orem. She seemed to improve for a week or ten days, but gradually sank and died in about three weeks.

It is interesting to note that the wound healed by primary union and no complications followed operation.

The patient died of inanition. An autopsy was earnestly sought, but her relatives refused. I am confident that this is one of those cases where tumors high up in the sigmoid had undergone carcinomatous degeneration. It is unfortunate that autopsy was refused.

The history of both cases points to an acute infection, and later the formation of these adenomatous tumors. I have previously reported two cases that underwent carcinomatous degeneration.

58 West Fifty-eighth Street.

The Stimulatory Action of the Oosperm in the Uterus.—J. Oliver presents an elaborate paper on this subject. He believes that no woman who has never menstruated ever becomes pregnant; this in spite of cases reported to the contrary. He says among other things that as long as the uterus is occupied by a product of conception menstruation is held in abeyance, and in the ordinary course of events parturition may be expected at any time between the 260th and 285th day after the date of the cessation of the last menstrual discharge, but without any apparent reason the pregnancy may be more or less abruptly terminated at any time. When, however, it becomes expedient to endeavor to cause the uterus to expel a product of conception which is still actively progressing, the greatest difficulty may be experienced in bringing about this result. The most reliable method is to introduce and leave for a greater or less length of time a solid bougie between the fetal sac and the uterine wall. By this means we so overexcite the uterus that this organ becomes intolerant of and expels its occupants. Here the operating agent imparts nothing to the uterus. An ecbolic is a substance which is supposed to exert such a direct chemical influence upon the pregnant uterus that the latter is thereby induced to expel its contents. There is, however, no known drug which acts thus. All the reputed ecbolics are toxic agents for which the uterus has no peculiar avidity, and when any of these chance to exert what appears to be an ecbolic action, it only influences the uterus indirectly and in virtue of some constitutional derangement which it causes. Ergot is probably, of all chemical agents, the drug which is credited with ecbolic power, but even this drug, when advisedly administered, is powerless to hasten the advent of labor or provoke abortion. It is, moreover, well known that reputed ecbolics sometimes kill the mother without abortion resulting. The anabolic activity of the pregnant uterus cannot be arrested by the administration of any known chemical substance. In conclusion, he ventures the opinion that while the germ mass at all stages of its existence abstracts from the mother all the materials which it requires for its development and growth, yet under normal circumstances the only waste product of the embryo or fetus which the mother is called upon to eliminate is carbon dioxide, because the product of conception until the fetus is mature is endowed with such resynthetizing powers that it is enabled to reassimilate over and over again its own by-products. If this is so—and there is evidence that it is so in the case of the chick in the egg—then no material passes from the embryo or fetus under ordinary circumstances except carbon dioxide, and for this reason the urine of the pregnant woman differs in no essential from that of any adult virgin.—*New York Medical Journal.*

MEDICAL RECORD.

CARDIAC SURGERY.

TEN years ago if a surgeon had stated that he had hopes of operating in the near future for aortic insufficiency or mitral stenosis, or if he had suggested a method of excising the arch of the aorta, his remarks would have been accepted as the exaggerations of a humorist. That a man should calmly and seriously consider such operations not only as possibilities but as probabilities of the near future would have seemed to the surgeon of a decade ago as an utter impossibility. Nevertheless during these first few years of the twentieth century such tremendous advances have been made both experimentally and practically in the spheres of thoracic and vascular surgery that in the July number of the *Annals of Surgery* Alexis Carrel of the Rockefeller Institute for Medical Research not only suggests the probability of intracardiac surgery being an accomplished fact in the near future, but even points out the technique of the various procedures which he believes will be developed in its performance.

A few months ago, when Meltzer and Auer devised their method of intratracheal insufflation as reported in the MEDICAL RECORD, by means of which animals, and more recently human beings, have been kept alive for hours without either active or passive respiratory movements, Carrel took immediate advantage of the work and began a series of experiments upon animals which has convinced him that cardiac surgery is a possibility of the future. After emphasizing the especial need of perfect asepsis required in thoracic surgery, owing to the low resistance offered by the pleura and pericardium to infection, Carrel describes the experiments which he has performed in the realm of cardiac surgery. In considering the surgery of aneurysm of the aorta two factors come into play, the treatment of the aneurysm and the integrity of the circulation during the operation. In the first of these much has already been done, the experiments of Matas and others pointing distinctly to possible methods of removing or curing the aneurysm. The real difficulty lies in the maintenance of the circulation, especially of the blood supply of the brain during the slow and delicate operations. To overcome this Carrel has devised two methods which he has called central and lateral diversion. As described by him "the central diversion consists of tubing the segment of the aorta which is to be resected. The vessel is laid open by a longitudinal incision and a paraffined tube is inserted into its lumen and temporarily fastened. This small operation involves only a short interruption of the circulation. Then the wall of the aorta can be extirpated and replaced while the circulation goes on through the tube. When the operation is completed the tube is removed through a small incision in the wall of the aorta. . . . It is a safe and convenient method for the descending aorta. It can be probably used also for the ascending aorta." The method of lateral diversion is even more daring and proportionally more dangerous. This consists, by means of a paraffined rubber tube or segment of jugular vein preserved in cold storage, in anastomosing the apex of the left ventricle to the descending aorta. This procedure by allowing the blood to reach the brain by a recurrent course upward through the descending aorta, the supply of course being shut off above, permits the complete obliteration of the arch for an indefinite period and the carrying out of any operation desired in this region.

In taking up the subject of intracardiac surgery, Carrel divides the possible operations into three classes: those which do not require hemostasis of the heart, those requiring hemostasis for a very short time, and those which require hemostasis for a longer time and stopping of the heart. In the first class come digital exploration of the auricle or ventricle, dilatation of the mitral valve, or incomplete ventriculectomy. Under the second class are suggested the insertion of tubes into the ventricles or auricles, the cutting of a stenosed mitral or tricuspid valve, or the curettage of endocarditic vegetation. Under the third class the author suggests plastic operations on the cardiac wall, and operations on the coronary arteries such as anastomoses and implantations for the cure of angina pectoris.

The mistake should not be made of inferring that Carrel is now prepared to perform all of these marvelous operations upon suffering humanity. He emphatically states that none of the procedures has as yet attained the technical perfection which warrants its application to the human being, and long and careful investigation will be required before aortic aneurysm and chronic endocarditis will be classed as surgical diseases. What he has done, however, is to place animals in such conditions that if they had suffered from intracardiac or aortic diseases, curative operations could have been performed, and he has shown that the accomplishment of this is not incompatible with life.

EHRLICH'S PREPARATION, NO. 606.

IT is very natural that the announcement of the discovery of an absolute and practically instantaneous cure of syphilis, as claimed by Ehrlich, should have aroused widespread interest among the general public as well as in the medical profession. Indeed, next to that of a specific for cancer, perhaps no discovery would be more welcomed by the laity than that of a cure for lues in any stage or

form and an immediate cure—a cure of syphilis while you wait, as it were. As told by our Berlin correspondent last week, this alleged specific is an arsenical preparation—dioxydiaminoarsenobenzol, to be exact, or dimethyldioxyarsenobenzoldichlorhydrate, to be perhaps more exact. It was obtained, not by accident, but after a long series of experiments and chemical operations, 605 indeed, the final successful product being therefore called 606; it is also called in honor of Ehrlich's assistant, Hata-preparation.

We need not review here the results of the early experiments with this remedy, for they are of a monotonous sameness, the preparation having already been employed in over 2,000 cases with apparent improvement, if not cure, in all. Whether, when the opening chorus of approval has subsided, some unsuccessful experimenters will be found who could not make themselves heard at first, the future will show. It was stated in all the early reports that the remedy had absolutely no bad effect on the human organism. It is, of course, possible—all things are possible, even a safe aeroplane—that a substance may be so poisonous to the protozoan parasite of syphilis, a bit of protoplasm, that it will destroy every one in the human body, yet will spare every cell and tissue of the host, but it is not probable. Atoxyl was thought at first to be innocuous to man while destructive to the trypanosome, but suddenly it was found to cause irremediable blindness, not to mention paralysis and other troubles. Two thousand men in central Europe may have as yet shown no ill effects from the remedy, but experience has taught us that the dangers of a new remedy are not always apparent at first. The dead from tuberculin bear mute witness to this fact.

Already Bohač and Sobotka, two Prague clinicians, raise a warning voice against a too complacent sense of security with regard to this remedy. They report in the *Wiener klinische Wochenschrift*, of July 28, three cases out of fourteen in which "606" was used, in which more or less alarming symptoms arose. In all these there was retention of urine from vesical paralysis, lasting from twelve hours in one case to over nine days in another, and in two of these there was a trace of albumin in the urine; in all three cases there was loss of the patellar and the other usually tested reflexes; in the three there was also complete obstipation; moreover in two rectal tenesmus was most troublesome. The authors note that these symptoms are very like those caused by atoxyl (not referring now to the blindness), a substance also containing, like the Hata-preparation, amidobenzol and arsenic groups. To this report Ehrlich telegraphed an answer published in the same journal for August 4. He does not deny the facts, but says that those to whom samples of the same make as that used by the Prague reporters were sent were unanimous in saying that they observed no such symptoms which proves or disproves nothing.

We cannot use the remedy in this country, for the reason that the Council on Pharmacy and Chemistry has not yet stamped it with its *sumatur*, and also incidentally because few if any samples have been sent out here. That is just as well. Our luetic patients can struggle on with mercury and the iodides for a while longer, and then, if their German fellow sufferers are not paralyzed or blinded and are found not to relapse, the manufacturers of this already patented remedy will see to it that the American wants are fully supplied at a fixed rate per phial.

Infant Mortality.

One of the most significant of the many phases of the world-wide movement of preventive medicine is the recent organization of the American Association for Study and Prevention of Infant Mortality. Founded as the result of a conference held last year at New Haven, this association will have its first meeting next November in Baltimore. The preparation for this meeting and the efforts that are to be made to interest the public and to secure its cooperation bid fair to make this organization a powerful factor in the modern struggle against early mortality. So far as the general public is concerned, interest in this subject is usually awakened during the summer months, when the death rate among infants reaches its highest point. Two factors are usually blamed for this increase: the prolonged hot weather and an impure milk supply. There can be no doubt that these are important exciting causes, but they are not the main and fundamental causes upon which the appalling slaughter of the innocents depends. The important factors which are either overlooked or entirely ignored are the evils of inherited and acquired disease, failure of maternal nursing, ignorance in the proper care of infants and in the management of their diet, frequent childbearing, and the host of evils that are included in the term poverty, chiefly overcrowding and wretched housing conditions. The efforts of municipal health authorities have properly been directed toward safeguarding the milk supply, and these efforts should be continued with renewed vigor. But attention to the milk should not divert one from the needs of the child. Similarly too great an emphasis is placed upon the hot weather as a cause of increased infant mortality. By lowering resistance in infants already debilitated by inherited or acquired disease or by insufficient or inappropriate diet, it operates somewhat in the same manner as the rigors of winter increase the death rate among the aged. But it cannot be too strongly affirmed that the problem of lowering the infant mortality is one not for the summer alone, but for the entire year. Its solution presents to practical sociologists an opportunity for planning and carrying on a comprehensive campaign for improving the condition of the poor. Not until this campaign has effected its object will the efforts of physicians succeed in markedly reducing the infantile death rate, unless they themselves are heartily enlisted in the sociological work. The key to the problem lies in education and enlightened philanthropy.

Fate of the Ehrlich-Hata Arsenical Preparation in the Body.

The fate of any substance possessing physiological and therapeutic activity, after it has exerted its activity, is of paramount importance. An inert soluble substance should be eliminated unchanged in

quantity. The physiological action of some substances like strychnine must be accomplished by an almost imponderable fraction of the ingested dose, as nearly the entire amount given may be recovered unchanged from the secretions, with nothing left behind in storage. Certain alien mineral substances ingested in excess are stored in minute quantities, chiefly in the liver; whence the occasional discovery of traces of arsenic, copper, etc., in residents of countries in which these elements are present in the soil and drinking water. In discussing the mode of action of the spirochete-annihilating arsenical preparation of Ehrlich and Hata, inquiry will naturally be made as to what becomes of the arsenic. The preparation is employed only in small quantities and it has been asserted that these quantities are promptly and satisfactorily eliminated. This statement is evidently, however, premature and based on insufficient observation. Alt (*Münchener medizinische Wochenschrift*, July 19) has already had two opportunities for autopsy on subjects treated with the new preparation and has learned from them as well as from clinical observation that the Ehrlich-Hata compound is eliminated much more slowly than its predecessors (atoxyl and others) when injected into the muscles. Atoxyl is eliminated promptly and almost completely by the urine, and this is also true of some of its congeners. On the contrary both the Ehrlich-Hata preparation and arsenophenylglycerin, which is used in combination with it, are not so promptly excreted by the kidneys, and may also be shown to persist for a number of days in the feces. The chief revelation of Alt's autopsies was that "606" remains unchanged for a long time at the site of injection, for he found that a considerable fraction of the medicament injected into the muscles had never been absorbed. There was, however, no evidence of any storage of the substance in the tissues which would seem to support Ehrlich's assertion that it is not organotropic.

Treatment of Typhoid Carrier Cases.

The fact that typhoid fever is frequently spread by means of individuals who carry the infection in their systems for considerable periods of time, sometimes for many years, is now definitely established. It is therefore considered that typhoid carriers are a definite menace to a community. It is obvious that it is a matter of great difficulty to discover typhoid carriers, and when these are discovered it is by no means easy to treat them successfully. In the *Journal of the Royal Army Medical Corps* for April, 1910, Cummins summarizes the results of treatment as follows: 1. Lactic acid bacilli have failed to diminish the excretion of typhoid bacilli. 2. Attempts to cure typhoid bacilluria by acidifying the urine have not been successful. 3. The administration of antiseptics has invariably brought about a decided diminution in the number of bacilli excreted, both by fecal and urinary carriers. 4. The use of *x*-rays, especially in cases with gall-bladder symptoms, seems to have a definite beneficial result, but as the author's experience with this form of treatment was limited to one case, his conclusions would appear to be of little value. 5. Lastly, it appears possible that treatment by a vaccine, though unsuccessful when tried alone in the cases now under discussion, would have a better chance if combined, in the case of urinary carriers, with diuretics, and in gall-bladder cases with *x*-ray treatment.

News of the Week.

Sanitation of the Canal Zone.—The report of the Department of Sanitation, Canal Zone, for the month of May, 1910, made by Dr. John L. Phillips, Acting Chief Sanitary Officer, shows that the annual death rate per thousand from all causes among the white employees for the month of May, 1910, was 9.94. For May, 1907, the rate was 18.34, and since that time there has been a steady decrease. The same rapid decrease is noted among the black employees, the death rate among this class being 34.48 in May, 1907, and 6.98 in May, 1910. Throughout the Canal Zone and the cities of Panama and Colon the rate during the months of May has been as follows: 1907, 31.57; 1908, 20.87; 1909, 15.77; 1910, 18.69. The number of employees in May, 1907, was 39,003, with 98 deaths; in May, 1908, 44,816, with 39 deaths; in May, 1909, 46,974, with 37 deaths; and in May, 1910, 52,863, with 34 deaths. Of these last, 6 were from tuberculosis, 2 from dysentery, and 1 each from black water fever, malarial fever, typhoid fever, and pneumonia. The total number of white Americans connected with the commission and the Panama Railroad during the month, including employees and their families, was 10,285; among these there were 6 deaths, 4 from disease and 2 from external causes, an annual death rate of 7 per thousand. Of malarial cases among employees discharged and died from hospital during the month there were 2 deaths and 618 discharges. No plague, smallpox, or yellow fever originated on or was brought to the isthmus during the month. The general sanitary conditions were reported as favorable, although the weather had been such as to further the development of mosquitoes and malaria; and the malarial sick rate for June may show the effects of this. During the month of May 1,807 rats were destroyed, and 6 houses were fumigated.

Deaths from Cholera.—During the week from July 31 to August 6 there were reported throughout Russia 20,668 cases of cholera with 8,679 deaths. One of the most serious features of the situation is the spread of the infection through the rural districts where the ignorance of the people makes them exceedingly hostile to modern methods of sanitation, and greatly hinders the efforts to check the disease. Both the Austrian and the German governments are taking precautions against the spread of the infection into those countries from the provinces of southern Russia where the epidemic is at its height.

An Investigation of Infantile Paralysis.—At the recent meeting of the Congress of American Physicians and Surgeons, held in Washington in May, 1910, a joint session of the American Orthopedic and American Pediatric Societies was held and the subject of epidemic poliomyelitis was discussed. The following resolution was adopted: "It having been shown by recent epidemics and investigations connected with the same that epidemic infantile spinal paralysis is an infectious communicable disease that has a mortality of from 5 to 20 per cent., and that 75 per cent. or more of the patients surviving are permanently crippled, State boards of health and other health authorities are urged to adopt the same or similar measures as are already adopted and enforced in Massachusetts for ascertaining the modes of origin and manner of distribution of the disease with a view of controling and limiting the spread of so serious an affec-

tion." A committee with Dr. Robert W. Lovett, *President*, Boston, Mass., Dr. Irving M. Snow, *Secretary*, Buffalo, N. Y., was appointed to urge the various State and municipal health authorities to take up the work of investigation of the various foci of epidemic poliomyelitis, to study its epidemiology, and to instruct the public that the disease is at least mildly communicable.

Moving Pictures as Health Aids.—Moving pictures are being used in the general campaign of educating the public to combat disease. In New Jersey a series of films are being prepared to show the working of a model dairy. The New York State Department of Health is preparing lantern slides for use in its lectures, which are procurable from local health officers. The same method has been pursued for some years in lectures on tuberculosis, and lectures on diphtheria, rabies, typhoid fever, and other diseases will now be illustrated in the same way. In Buffalo the acting Health Commissioner has prepared slides which are flashed on the screen at moving picture shows, giving warning that whooping cough is dangerous, and that adults as well as children may be affected.

Immigration Slackens.—Statistics for the month of July, the first month of the fiscal year, show a decided slackening in immigration. At Ellis Island 52,727 immigrants arrived, the Italians outnumbering all the others, with the Jews, chiefly from Russia, second.

Food Purity Guarantee.—The Government of Venezuela has been requested by the State Department to suspend the operation of its new regulations requiring certificates guaranteeing the purity of food products sent to Venezuela from this country. It is hoped that an agreement between the two countries may be reached by which the present strict regulations of the Department of Agriculture will be sufficient guarantee.

King Visits Hospital.—The first public appearance of King George and Queen Mary of England since their accession was the occasion of a recent visit to the London Hospital in Whitechapel, the London east end.

Mayor Gaynor.—The last official act of Mayor Gaynor before the murderous attack upon him was the signing of himself as one of the incorporators of a new hospital at St. James, Long Island.

To Close Children's Home.—It is reported that lack of funds may make necessary the closing of the Watts De Peyster Home for Invalid Children, at Verbank, near Poughkeepsie, N. Y. The home has been in existence for twenty-five years, and cares for nearly a hundred children frow two to twelve years old for the entire year.

University of Pennsylvania.—With the opening of the coming fall session an elective course in tropical medicine will be offered under the immediate charge of Dr. Allen J. Smith, in conjunction with Dr. A. C. Abbott, Dr. G. E. de Schweinitz, Dr. William Pepper, Dr. W. H. Hartzell, and Dr. H. H. Jacobs. The course will comprise instruction in medical climatology and geography, the hygiene of ships and of the tropics, protozoology, anthropology, helminthology, general medical pathology, diseases of the eye and of the skin, surgical diseases common to the tropics, pathology of tropical diseases, and systematic and clinical tropical medicine.

Dr. Willis F. Manges has been appointed director of the Röntgen Ray Laboratory of the Philadelphia General Hospital in succession to the late Dr. Mihran K. Kassabian.

Gifts to Charities.—The will of Mrs. Elizabeth Waddington of New York, who died recently, provides for the gift of $5,000 to St. Vincent's Hospital to endow a bed in memory of Euphemia Van Rensselaer.

The contest over the will of the late John Masterton Burke of New York was dismissed by Surrogate Thomas on August 9. By the terms of the will $4,000,000 was left to the Winifred Masterton Burke Relief Foundation to found a home for convalescents. The contest was brought by certain heirs on the basis that the statute of 1904, authorizing the corporation, was invalid on technical grounds. The Surrogate holds that the statute is constitutional and that the gifts to the foundation are valid. The home is to be a memorial to Mr. Burke's mother.

The Harvey Society.—The following program of Harvey Society lectures for the season of 1910-1911 is announced: 1910—October 15, "Die Bedeutung der pathologischen Autopsie und sonstiger pathologisch-anatomischen Untersuchungen," by Prof. Dr. H. Chiari of Strassburg, Germany; November 12, "Unit Characters in Heredity," by Prof. W. E. Castle of Harvard University; December 10, "Certain Clinical Aspects of Dyspituitarism," by Prof. Harvey Cushing of Johns Hopkins University, Baltimore. 1911—January 14, a lecture on some subject to be announced later, by Prof. Arthur R. Cushny of the University of London; February 4, "The Chemistry of the Proteins," by Dr. Thomas B. Osborne of the Connecticut Agricultural Experiment Station, New Haven; February 25, a lecture on a subject to be announced later, by Prof. Jacques Loeb of the Rockefeller Institute for Medical Research; March 18, a lecture on a subject to be announced later, by Prof. H. Gideon Wells of the University of Chicago. These lectures are open to the public and a cordial invitation is extended to all to attend. They are given in the New York Academy of Medicine, 17 West Forty-third street, on Saturday evenings. The officers of the society are: *President*, Dr. Simon Flexner; *Vice-President*, Dr. John Howland; *Treasurer*, Dr. E. K. Dunham; *Secretary*, Dr. Haven Emerson; *Council*, Dr. Graham Lusk, Dr. S. J. Meltzer, and Dr. James Ewing.

The Washington State Medical Association closed its annual session, on July 29, with the election of the following officers for the ensuing year: *President*, Dr. Wilson Johnson, Spokane; *Vice-President*, Dr. L. L. Love, Tacoma; *Secretary*, Dr. C. H. Thomson, Seattle; *Treasurer*, Dr. Park Weed Willis, Seattle.

The Washington State Eclectic Medical Society held its annual meeting, on August 2, at Seattle. The following officers were elected: *President*, Dr. Thomas J. Piersol, Tacoma; *Vice-President*, Dr. Frank Brooks, Seattle; *Secretary*, Dr. N. M. Cook, Seattle; *Treasurer*, Dr. L. V. Cole, Seattle.

Medical Society of the Missouri Valley.—The twenty-third annual meeting of this society will be held in Council Bluffs, Iowa, on Thursday and Friday, September 1 and 2, under the presidency of Dr. A. B. Somers of Omaha. Dr. George Gellhorn of St. Louis will deliver the oration in surgery, which will be illustrated with lantern slides. The oration in medicine will be delivered by Dr. George Howard Hoxie, Dean of the Medical De-

partment of the University of Kansas, the subject being "Arthritis." The secretary of the society is Dr. Charles Wood Fassett of St. Joseph, Mo. At the close of the scientific program on Thursday evening, the members will be entertained at a smoker at the Grand Hotel.

Association des Médecins de Langue Française de l'Amerique du Nord.—The Fifth Congress of this society will be held at Sherbrooke, Quebec, on August 23, 24, and 25, 1910, under the presidency of the Hon. P. Pelletier. Dr. L. Picqué of Paris, the official representative of the French Society of Surgery, will attend the congress and deliver an address. Dr. F.-A. Gadbois of Sherbrooke is the secretary-general of the society.

Obituary Notes.—Dr. Seymour J. Holly of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons of New York in the year 1857, a veteran of the Civil War, and formerly an inspector in the Brooklyn Department of Health, died at his home in Brooklyn, on August 7, after a long illness.

Dr. James I. Wright of Philadelphia, Pa., a graduate of the Jefferson Medical College of Philadelphia, died at his home on July 27, aged 58 years.

Dr. J. Warren Boyer of Trappe, Pa., a graduate of the Jefferson Medical College of Philadelphia in 1845, died at his home on July 24, at the advanced age of 90 years.

Rear-Admiral Walter Keeler Scofield, U. S. N., retired, died recently at his home in Stamford, Conn., aged 71 years. Dr. Scofield was graduated from the College of Physicians and Surgeons of New York in 1868. He entered the United States Navy as an assistant surgeon and passing through the successive grades was made a Medical Director in 1890. In 1901 he retired from the service with the rank of Rear-Admiral.

Dr. Charles R. Strong of Detroit, Mich., a graduate of the Detroit College of Medicine in 1903, died in the Red Cross Hospital in that city on August 1.

Dr. Irving O. Cummings of Brewster, Mass., a graduate of Dartmouth College and of the Harvard University Medical School in 1890, died of Bright's disease at his home on August 2, aged 42 years.

Dr. Alexander J. Stone of St. Paul, Minn., a graduate of the Berkshire Medical College, the medical department of Williams College, in 1867, died at his home recently.

Dr. William F. Ridgway of Atlantic City, N. J., died at his home, on August 5, aged 38 years. Dr. Ridgway was graduated from the Jefferson Medical College, Philadelphia, in 1904, and after post-graduate courses at the West London Hospital and the Rotunda Hospital of Dublin, took up his practice in Atlantic City, becoming pathologist to the Atlantic City Hospital and city physician. He was a member of the Atlantic County and New Jersey State Medical Societies, the American Medical Association, and the Atlantic City Academy of Medicine.

Dr. D. W. Rees of Needles, Cal., a graduate of the California Medical College (Eclectic), San Francisco, died in a hospital at Los Angeles, from poisoning resulting from an ulcerated tooth, on July 31, aged 41 years.

Dr. Henry F. Koester of New York, a graduate of the Bellevue Hospital Medical College in 1891, and a member of the New York County and State Medical Societies, died at his home, on July 28, aged 47 years.

Obituary.

FLORENCE NIGHTINGALE.

Florence Nightingale, who died last Sunday afternoon at her home in London, was born in Florence, Italy, from which city she took her name, on May 12, 1810, her father being a wealthy Englishman, a member of the numerous English colony in that beautiful Italian city. The family returned soon to England where the girl received an unusual education. She was from childhood devoted to charitable work among the cottagers on her father's estate, and was also interested in hospital work, spending a considerable portion of her annual vacation in visiting the hospitals in Germany. In 1851 she entered the training school for Lutheran Sisters at Kaiserwerth and later studied the nursing methods of the Sisters of Charity in Paris.

In 1854, when the English soldiers were perishing of disease in the Crimea with none but rough men to nurse them, the people of England cried out in rage, and the Government was forced to send them succor. The head of the War Department turned at once to Miss Nightingale, whose activities were well known, and curiously his letter asking her help crossed one from her offering her services. Soon after, she set sail at the head of thirty-four nurses, reaching the Crimea just after the battle of Inkerman. There, in spite of opposition from the officers and surgeons as well, she put the hospitals in order and cleaned them, established invalid kitchens, laundries, and libraries, transforming the entire camp indeed, finally winning to her side every man, sick or well, from the Commander-in-Chief to the last drummer-boy, who one and all called her the "Angel of the Crimea."

When Florence Nightingale returned to England she was suffering from the debility following an attack of cholera at Sebastopol, and slipped into the country incognita in order to escape the reception that was planned for her. Balked of their desire so to honor her, the people gave her a purse of a quarter of a million dollars raised by popular subscription. She accepted it and with it established a training school for nursing in London. She was at the head of this school for nearly twenty-five years, when delicate health forced her retirement. From that time her life became one of great quiet and she passed from the public gaze, but not from the memory of those who love the lovers of their kind, and there was a constant pilgrimage to her home of admirers and followers from two continents. Her Government did not forget her. In 1907, on the birthday of the Queen, King Edward conferred on her the English Order of Merit, she being the only woman who had ever received it, and the following year the freedom of the City of London was bestowed on her. She was also made a member of the Order of Our Lady of Grace of St. John of Jerusalem. Florence Nightingale's personality was most lovable. "Of her kindness," said the *Lancet* in a recent notice, "her gentleness, her marvellous influence over her patients, of her firmness, her energy, her untiring devotion, we need not speak. Are they not written in the book of the chronicles of the British nation?" Fate was kind to her in that she lived to see the seed she had sown in the Crimea and in the London training school grow into a mighty tree with branches spreading over the civilized world.

Correspondence.

TREATMENT OF RHUS POISONING.

To the Editor of the Medical Record:

Sir: Apropos of Dr. Ellis's letter on Poison Ivy Rash that appeared in a recent issue of your publication, I would call the attention of the profession to the one remedy in my opinion (used in conjunction with some minor ones) and that is the good old-fashioned lead and opium wash, improved. The improvement is a solution of boracic acid 10 grs. to the ounce of distilled water as a base, grs. 5, acetate of lead, and in place of powdered opium, the U. S. P. liquor morphinæ sulphatis. This improvement does away with the unpleasant odor and staining properties of the ordinary lead and opium wash. The substitution of the liquor morphine sulphatis, U. S. P., for the powdered opium and water is not original with me, but the credit as far as I know belongs to Prof. Wm. H. Thomson of New York.

The directions are as follows: After the initial cleansing of the affected parts with a 1-40 solution of carbolic acid and any good laundry soap, water is not again to be used during the treatment. If for any reason the affected parts have to be cleansed, carbolized oil is to be used, applied on absorbent cotton. Apply the improved lead and morphine lotion on antiseptic gauze and on parts not convenient to bandage apply the lotion and dust with camphorated sterate of zinc. This dusting powder is not only soothing, but helps to control the oozing, thereby preventing the spreading of the rash. At bedtime advise patient to wear loose cotton gloves, if for any reason the hands cannot be bandaged. This last measure will often prevent the spreading of the rash to the eyes and genital organs.

Internally I use small doses of aconite and gelsemium, for the fever and nervous disturbance, and calomel, ipecac, and bicarbonate of sodium, following the latter with a heaping teaspoonful of sulphate of magnesia in one-half a glass of water before breakfast. I sometimes add to the same quantity of Epsom salts an equal amount of cream of tartar. Of course if these quantities cause the bowels to move too freely, reduce the amount so that the patient will have two or three good movements a day.

In conclusion I will say that in a practice of over 25 years in a part of the United States where poison ivy rash is very common I have met with few cases that the treatment as outlined has not speedily and almost painlessly cured; and this too, after most of my patients have used the ordinary home remedies, such as salt water, white lead, spirit of nitre, aqua ammoniæ, etc. In my opinion the failures that have been charged to acetate of lead have been due to the fact that the solutions have been applied entirely too strong, thereby causing a great deal of pain and an increase of the inflammation of the skin.

C. H. Gardner, Ph.G., M.D.

Spruce Creek, Pa.

DESIRABILITY OF EXCLUDING CONTAGIOUS DISEASES FROM DISPENSARY CLINICS.

To the Editor of the Medical Record.

Sir:—From a sanitary point of view patients, especially children, suffering from contagious diseases, should be excluded from dispensary clinics. As anybody who has worked in a dispensary knows, patients sit close together while waiting for treatment and often have to wait from one to three hours before they are treated. Mothers who bring sick children often bring healthy children along, thus unknowingly exposing the latter to infection from their own or other people's sick babies. Examining tables and chairs are used continuously so that infection lingers on them and is transmitted to succeeding children. Furthermore, children brought to dispensaries are below par and unusually susceptible to contagion.

These conditions have been recognized in Mt. Sinai Hospital Dispensary, and physicians have been appointed to give all children who apply for treatment a preliminary examination to find if any suffer from contagious diseases. If such are found they are sent home and their condition is reported to the Board of Health. The following figures illustrate the need of exclusion. During the six weeks from May 16 to June 30, inclusive, in the afternoon classes there were excluded 96 cases of contagious diseases. The total number of children who were brought for treatment was 1661, of whom 1083 came for the first time. The number of exclusions would have been larger but for the fact that many pertussis cases were not recognized, since I did not hear the cough. The contagious cases were distributed as follows: Scarlet fever, 19; measles, 12; diphtheria, 12; varicella, 18; rubella, 11; parotitis, 6; pertussis, 17; erysipelas, 1.

An interesting feature of these figures is the fact that eight of the twelve diphtheria cases were cases of nasal diphtheria. The condition of the nose in these cases varied from that in which there was only a thin serous discharge to that with profuse bloody, purulent discharge and severe excoriations of the upper lip. The former were the more numerous. This teaches that all nasal discharges should be looked on with suspicion.

Max Unger, M. D.

53 East Seventh Street, New York.

EXPERT TESTIMONY.

To the Editor of the Medical Record:

Sir:—While reading the very excellent article in your issue of July 23 by Dr. Carlos F. MacDonald on "The Ethical Aspects of Expert Testimony in Relation to the Pleas of Insanity as a Defense to an Indictment for Crime" an idea came to me which it seems to me would be a help in solving the problem. Not that it would do away with the desirability of acting on Dr. MacDonald's suggestions of working up a set of rules governing expert testimony and putting them in the Code of Ethics, refusing to allow the medical assistant to the attorneys to testify, and getting a new legal definition of what constitutes mental irresponsibility; but that it would be another help in getting true justice for the prisoner and the State and putting medical expert testimony on the high level on which it belongs.

My suggestion is that while the medical experts are to be selected by the rival attorneys, as at present, they are to be engaged either by the judge or a clerk of the court and not allowed to know which side is engaging them. There would thus be no limit to the number and no restriction to the personnel of the experts except in the case of those helping the attorney; the compensation would have to be the same, regardless of the testimony and the side suggesting each expert could pay him, but through the court, and there would not even be the unavoidable bias of judgment of the present method of looking at everything from the one side, but each expert would look from all sides, and we would get as near a perfectly just view as is often given to poor, weak humanity.

C. H. Church, M. D.

Newark, N. J.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE BRITISH MEDICAL ANNUAL MEETING—PRESIDENT'S ADDRESS — MEDICAL ADDRESS — SECTIONS — PHARMACEUTICAL CONFERENCE—ITEMS—OBITUARY.

London, July 29, 1910.

The proceedings of the British Medical Association have followed the course of the program described in my letter last week. The representative meeting has considered the proposals of the leaders and endorsed them, giving occasion to the non-contents to sneer at the ruling clique and decry the trade-unionism which they say is the chief feature of the association, and which to some degree must be admitted to exist. But this is largely the fault of the mass of members who seem to be indifferent to matters of medical politics either within or without the association. The written constitution of the association is democratic enough to prevent the development of an oligarchy so long as the majority of the members do not contribute to such a result by their indifference.

Mr. Butlin delivered the presidential address on Tuesday evening, taking for his text the evolution of the association and its work. He gave a series of word pictures beginning with Lister and coming down to the present day of prosperity. He extolled the efforts made to attain medical reform, including the last act, which gave direct representation, but he did not point out how useless that had been so far, and he did not seem aware that the final movement of the council of the association in obtaining it was stained with political trickery which was everywhere felt to be a scandal. In his conclusion he spoke of the vast amount of gratuitous work which has been so freely given by the profession in all times, until the more ignorant populace have come to think that there is some legal or conventional obligation on a doctor to be ready at all times to hasten to the afflicted poor without any

fee or reward. He saw the danger of multiplying doctors for whom there is little prospect of their earning a living.

On Wednesday the chief attraction was the "Address in Medicine," which was delivered by Dr. Mitchell Bruce. The traditional mode of treating this address is to review the advances since the last meeting, but Dr. Bruce preferred to look at the progress made since the last meeting in London, 15 years ago. This he did to show the dominant position achieved by etiology, a theme which he elaborated at great length, to emphasize the fact that the outstanding feature of the medicine of to-day is the study and practical application of etiology, with respect not only to the nature and incidence of the specific causes of disease, but to the nature of immunity and the circumstances under which it fails. He pointed out, too, how the knowledge acquired by the family practitioner contributes his share of the materials on which etiology is based as much as the few who are able to devote all their work to the higher pathogeny.

The numerous sections afford opportunities for clinical and scientific discussions which appear on paper abundant, but which in practice are limited by the mass of material. As an illustration of this, take the new section on anesthetics. You will remember that arising out of former meetings a special committee on chloroform, consisting of eminent experts, has for years been at work and has made interim reports. Well, the final report of this committee has now been agreed upon. It fills above 20 pages of a supplement to the journal and was issued in advance as obviously if read in the ordinary course it would occupy all the time to the exclusion of discussion. In this way other experts have been able to digest the document, compare with their own experience and so submit their several conclusions. Accordingly the report was taken as read and the discussion, if so we may call it, began on Wednesday with two papers read by Dr. D. Buxton and Prof. Waller, both members of the committee.

These two lengthy communications set forth the respective authors well-known views—the percentage system and the plenum apparatus being their principal points. The second day's discussion likewise was begun by two set papers on shock during anesthesia, one by Dr. Crile, whose work on this subject must be well known to your readers.

Sympathy with Dr. Dawson Williams was expressed and in reply a letter of thanks showed that he was progressing favorably.

The Pharmaceutical Conference has been held during the week at Cambridge and received with no little attention by the university and the corporation.

While we are shivering in an extraordinarily inclement summer we read of your oppression under a heat-wave. When a telegram gave your temperature as 100 F. my thermometer hardly touched 60. Yesterday a change set in and we are hoping for the deficiency of sunlight to be made up to us.

The London Hospital is to be honored to-morrow by a visit from the King and Queen. As this is the first public drive taken together by their majesties much interest is felt in the event, especially as it is to the great East End hospital.

Liverpool University benefits, among many other institutions, under the will of Mr. T. S. Timmis to the extent of £10,000 to endow a cancer research department of its laboratories.

Surgeon Moyle Breton, R. N., who had been invalided from the Service on account of illness has died at a nursing home, aged 41. He was a St. George's student, took the M. R. C. S. in 1895, and two years later entered the naval medical service. He was appointed surgeon to the "Victory" at Portsmouth in 1904.

Dr. J. Bart Rous who died on the 12th from morphia, was a London graduate with honors, who took to journalism and was for some time on the staff of the "Lancet." He had suffered from nervous disease, was a very active man and a great favorite among his fellow students and colleagues.

Infant Feeding.—Steinhardt calls attention to the problems related to infant feeding. A large number of medical men think infant feeding too simple to give it their attention, and this often results in the unnecessary sacrificing of infants. Infant feeding is really a very important branch of medicine, and all medical men should know how to feed a child normally. The stools should be very carefully examined because they tell us what component is to be changed.—*Crónica Médico-Quirúrgica de la Habana.*

Progress of Medical Science.

Boston Medical and Surgical Journal, August 4, 1910.

The Incidence of Heart Disease in Acute Psychoses.—Albert A. Horner summarizes his investigations by the following statements: (1) The percentage of hearts probably normal functionally is higher in manic-depressive insanity than in dementia precox. (2) Dilatation of heart occurs more frequently in manic-depressive insanity than in dementia precox. (3) Leaving out dilatation of the heart, the incidence of every cardiac lesion in dementia precox is greater than the incidence of the corresponding lesion in manic-depressive insanity. (4) The incidence of individual heart lesions is relatively greater in the acute psychoses than in all psychoses combined, except that the relative frequency of hypertrophied hearts in manic-depressive insanity is below the average. (5) This study suggests the desirability of a close clinical study of hearts, pulse and blood tension in the group of acute psychoses.

Mannite and Nonmannite Fermenting Organisms in a Case of Dysentery, Complicated by Hemorrhagic Endometritis Probably Due to a Third Organism.—Myrtelle M. Canavan reports the case of a woman 61 years of age, who was supposed to have had cerebral hemorrhage before coming to the hospital. Immediately after her admission she passed uninfected through an epidemic of dysentery, but nearly a year after her admission she died after an illness of twelve days preceded by simple diarrhea, during which time her serum did not agglutinate the stock cultures of *B. shiga* and *B. flexner*. A careful autopsy showed that the most striking lesions accompanying the dysentery were abscesses of the lungs, infarct of the spleen, thrombus of the iliac artery and acute hemorrhagic endometritis. From the fundus and cervix the third organism was present in abundance of colonies and is identical with the "organism to be specially studied," isolated from the blood and mesenteric lymph nodes in the case of "ulcerative vaginitis complicating a case of dysentery in the epidemic of 1908," *i.e.* a Gram negative bacillus, which does not produce gas, peptonizes milk, produces indol, is motile, liquefies gelatin and has a bleaching and coagulating action on the litmus sugar-serum-water of Hiss; is not agglutinated by antidysenteric serum. The relation of this bacillus to hemorrhages, small and great, seems more than a coincidence, since it has been recovered from hemorrhagic cystitis, submucous hemorrhages in gastric and vaginal walls, in bloody mucus in the intestinal tract, etc.

Some Effects of Overfeeding with Fats in Certain Cases of Insanity.—Herman M. Adler says that the organism has provision normally for converting the fatty acid products of digestion into neutral fats. This power may be diminished under certain circumstances. In those cases in which fatty acid is not entirely converted into neutral fats, the toxic effects of the fatty acids are neutralized in other ways. One method by which free fatty acid is neutralized is by conversion into insoluble soap and when this occurs the body suffers a depletion in its calcium and magnesium content.

New York Medical Journal, August 6, 1910.

A Study of the Leucocytes in Pulmonary Tuberculosis.—Myer Solis-Cohen and Albert Strickler undertook an investigation to determine whether the leucocytes in cases of pulmonary tuberculosis in a sanitarium a little above sea level present a constant picture in the various stages of the disease and in accordance with the improvement or retrogression of the patient. The following conclusions are suggestive: 1. The percentage of polymorphonuclear neutrophiles was diminished in incipient and moderately advanced cases, being less in the former. It was also diminished in cases that were improving. 2. The percentages of the different forms of polymorphonuclear neutrophiles, classified according to the number of nuclei they contained, bore no constant relation to any stage or to the progress of the disease. 3. The percentage of lymphocytes was increased in incipient and moderately advanced and in improving cases. 4. The percentage of large mononuclear and transitional cells, grouped together, while within normal limits, was greater in incipient and in improving cases. 5. The percentage of eosinophiles was greatest, though normal, in incipient cases. 6. In moderately advanced cases was found the lowest percentage of large mononuclear and transitional cells, grouped together, and of eosinophiles, and the highest percentage of large mononuclear cells. 7. In patients whose condition was stationary occurred the highest percentage of polymorphonuclear neutrophiles, and the lowest percentage of lymphocytes, of large mononuclear cells, and of large mononu-

clear and transitional cells grouped together. 8. Whenever one extreme was exhibited by moderately advanced cases (as in 6) or by stationary cases (as in 7) the other extreme was furnished respectively by incipient cases or by improving cases. Far advanced and retrograding cases respectively held a middle position, which approached the condition found in incipient and in improving cases respectively, rather than the other extreme. 9. In addition to the mononuclear basophilic cells, the blood occasionally contains polynuclear basophilic cells, easily distinguishable from other leucocytes.

Lane's Conception of Chronic Constipation and Its Management.—A. B. Cook says that the two chief pathological factors concerned in the production and maintenance of chronic constipation are enteroptosis and acquired mesenteries or adhesions. These adhesions do not result from inflammation, but are developed to oppose the displacement of viscera, the tendency to which exists whenever the erect posture of the trunk is assumed. This is the basic feature of Lane's theory. The gross changes produced in the several portions of the large intestine are described. The symptoms are those produced mechanically by the changes in the gut, and those due to absorption of toxic elements from the retained matter. According to Lane's teaching a proper conception of diseases of the appendix, gall bladder, stomach, duodenum, pancreas, kidneys, ovaries, etc., in many cases requires that they be regarded as sequelæ of chronic constipation. In no circumstances should operative interference be contemplated till the surgeon has satisfied himself that every means of treatment has failed, whether medical or mechanical. In the milder type of cases in which non-operative means have failed to afford relief, the division of all the constricting bands and adhesions, together with careful attention to the bowel function, may prove effective. In the severer cases more radical surgery will be required and this consists in dividing the ileum three to five inches from its junction with the cecum and anastomosing the proximal end with the sigmoid or upper rectum, thus short-circuiting the fecal current and eliminating the possibility of further toxic absorption. When pain is a prominent factor it is often necessary to remove the colon in part or in whole, preferably the latter. Cook believes that Lane's conception of chronic constipation and its management will be found to be the most nearly correct in principle and practice of all the numberless "new views" with which the literature of the subject is burdened.

Journal of the American Medical Association, August 6, 1910.

The Rôle of Otology and Rhinology in Preventive Medicine.—John J. Kyle treats of the ear, nose and throat in etiology and claims that the prevention of many of the diseases enumerated depends on the application of the rules of hygiene, frequent cleansing of the nose with mild antiseptic and alkaline solutions, free nasal drainage, and good general hygienic surroundings. The size of the tonsils has nothing to do with cervical adenitis and general infection. Jonathan Wright states that "tuberculous cervical glands at the angle of the jaw are almost always secondary to primary tuberculosis of the tonsil." Marked benefit often follows the removal of the tonsils in cases of pulmonary tuberculosis in the early stages, in which tubercle bacilli are easily demonstrated in the sputum. The direct connection of the cervical glands with the apices of the lungs makes it comparatively easy for the tubercle bacilli to seek the point of least resistance, which is the apex of the lung in many cases. It seems reasonable that in all suspected cases of pulmonary tuberculosis the tonsils should be inspected, and if possessing the slightest evidence of possible irritation, should be removed in their capsules. Many laryngologists recognize a close relationship between acute tonsillitis and rheumatism. Many conditions such as endocarditis, meningitis, nephritis and appendicitis are reported as probably originating from a disease of the tonsils in certain specific cases. Since the tonsils are a possible menace to the general economy, it would be better to remove at the earliest possible moment those tonsils which are hypertrophied whenever observed in young children to produce mouth breathing, and if the cervical glands are enlarged even small tonsils should be removed. Inflammation and hypertrophy of the tissue in the vault of the pharynx predispose to recurrent attacks of postnasal infection, deformities of the face, mouth breathing, deafness, Balnes' cough or nocturnal cough, infectious diseases, and Sydenham's chorea. A progressive deafness with or without tirnitus is especially important as an etiological factor in general nervous exhaustion and many functional nervous disorders.

The Uselessness of Local Treatment in Puerperal Sepsis.—The following summary is offered by J. H. Carstens: 1. In puerperal sepsis local treatment is of no benefit. 2. Douches and intrauterine irrigation often do harm. 3. Local abscesses should be opened and allowed to drain without irrigation. 4. Constitutional treatment, on general principles, should be instituted, quinine and opium being the sheet anchor. 5. Elimination in every direction should be assisted. 6. The infecting organism should be identified and the opsonic index increased by antitoxins. 7. And, after all, prevention should be our constant endeavor, a clean patient and clean doctors and midwives; this is most often secured by wearing rubber gloves.

Chronic Influenzal Bronchitis.—J. D. Madison reports cases to illustrate the different phases of chronic influenzal bronchitis. All the cases reported show other organisms than the influenza bacillus in the sputum. The symptomatology of influenzal bronchitis does not differ materially from that of chronic bronchitis produced by other organisms. The not infrequent occurrence of hemoptysis is worthy of note. The prognosis in cases of bronchitis of years' standing, usually with bronchiectasis, is, as a rule, bad. Usually a few weeks of outdoor life in a warm, genial climate, if possible, is sufficient to remove the condition.

The Teeth as an Important Factor in Pathogenesis.—H. A. Potts says that the immediate pathological conditions caused by unerupted temporary teeth are very few. The diseases the cause of which has been attributed to the eruption of the temporary teeth are legion. Difficult dentition gives rise to reflex symptoms. The fully erupted temporary teeth are subject to the same conditions as those which affect the permanent teeth, and give rise to a long chain of pathological conditions. Many a child has spent a sleepless night on account of an irritated tooth-pulp. Cervical and lymphadenopathy are undoubtedly due to absorption of toxins. Arthritis may be caused by infection harbored by the teeth or caused by pathological diseases of the teeth. There are many complications and sequelæ following the death of a tooth-pulp, and foremost is the formation of an alveolar abscess, which is essentially an osteomyelitis. The extraction of a tooth which gives rise to an alveolar abscess is at times contraindicated: extraction only intensifies the result of the infection. After the crowns of the temporary teeth have been destroyed by caries the roots form receptacles for the retention of putrefactive substances. Much that has been said in regard to the temporary teeth applies as well to the permanent teeth. Before eruption the teeth give rise to cysts and tumors. The most frequently occurring cysts of the jaws are the root cysts which develop from the granulomata at the ends of the roots, whose pulps have been destroyed through caries and exposures. Multilocular cysts and the benign solid epitheliomata belong to the same class, the former springing from the enamel organ, the others being a development of one or all of the individual elements of the tooth follicle. Non-erupted teeth cause reflex disturbances referable to almost any of the cranial nerves, also taking in a much wider scope, namely, that of impaired mental condition. Of the myriads of bacteria found in the mouth, only a few can be said to be indigenous: this points to the importance of cleanliness of the mouth and teeth. Malocclusion gives rise to many deplorable conditions which could have been avoided had the mouth been in the care of a competent dentist, especially at the time of eruption of the sixth-year molars. The dentists should be able to cope with any pathological condition in the mouth, thereby attacking disease many times in its inception, when it is easy of eradication.

The Lancet, July 30, 1910.

The Pathology of Prostatic Enlargement.—F. T. Paul discusses the various theories offered in explanation of the pathology of prostatic enlargement and traces the analogy between the involutional changes met with in the female breast at the climacteric period and those changes occurring in prostatic enlargement and summarizes as follows: (1) The accepted theories as to the cause of prostatic hypertrophy all fail because each can apply only to a limited number of cases. (2) The prostate and the breast are both controlled by their respective dominant sexual glands and respond to their influence in a similar way in health and disease. (3) Both organs are subject to a disturbing influence at the climateric period, which may, and frequently does, result in a hypertrophic change. (4) In such change the microscopical appearances in the two organs show a remarkable resemblance in all the essential details. (5) Prostatic hypertrophy, like the mammary involution hypertrophy, occurs only at the climacteric period, whereas there is no known neoplasm which is so strictly limited

to any age period. For these reasons the author believes that prostatic hypertrophy is not due to a chronic inflammation of septic or specific type nor to a neoplasm, but that it is an involution change similar in character to that with which we are familiar in the mammary gland.

Helminthic Infection and Its Relation to Eosinophilia.—G. Duncan Whyte describes the work which he undertook in order to ascertain whether the *Clonorchis sinensis* is or is not responsible for any degree of eosinophilia. He finds it difficult to secure an adequate number of cases of unmixed infection with this parasite, and in cases of mixed infection it is impossible to determine exactly what proportion of the eosinophilia is to be attributed to each of the parasites present. The study is based upon the examination of the feces of 562 cases and of the blood of 102 cases in South China. In only 2.1 per cent. of 512 cases examined did the feces fail to show the ova of one parasite or another. Ascaris lumbricoides was present in 76 per cent. of the cases; trichocephalus trichiuris in 72.6 per cent.; ankylostoma duodenale and uncinaria americana, one or the other, in 60.4 per cent. A large proportion of those infected by the latter parasites were farmers. *Clonorchis sinensis* was found in 16 per cent. of 267 cases examined at Chao-chow-fu and only 2 out of 295 cases at the hospital at Suabue were found infected, and these came from the Chao-chow-fu district. From a study of the results of these examinations it seems that the more varieties of parasite that infest a man, and the more numerous the individuals of each variety, the greater degree of eosinophilia he is likely to show. This will be especially marked if he is between 20 and 40 years of age and will be less noticeable if he is older or is suffering from some form of tuberculosis.

The Successful Treatment by Colon Lavation of Some Cases of Eczema, Psoriasis, Urticaria, Acne and Pruritus.—Alfred Mantle shows that these affections may be due to autointoxication, the results of changes in metabolism of gastric or more frequently of intestinal origin. The benefit derived from colon lavation in certain cases suggests that the skin disturbance is more frequently associated with toxic absorption from the bowel than from the stomach, though doubtless the two absorptions are frequently associated. Gastroenteric toxins seem to have a special affinity for the vasomotor centers and consequently circulatory disturbances are common with disorders of the alimentary canal. The writer cites a number of cases of these affections which he treated successfully, especially where there was an associated colitis, by intestinal lavation with alkaline sulphur water, using 20 to 40 ounces of the sulphur water at a temperature of 105° F. with a pressure of two feet. A warm immersion bath of sulphur follows the douche and the patient is given sulphur water to drink each morning. The patients are advised to continue the treatment at intervals even after an apparent cure has been obtained.

British Medical Journal, July 30, 1910.

Acute Edema of the Lungs Treated with Belladonna.— L. Gwillim Davies reports the case of a man 47 years of age whom repeated attacks of gout had left with a quickened heart, but with no obvious dilatation or bruit. In response to a sudden call he found the patient *in extremis*, suffering from severe dyspnea, with uncountable pulse, heart beat of 125, rapid respiration, the accessory muscles of respiration being in action and moist râles being present everywhere over the chest, back and front. The man coughed up a peculiar froth of pinkish color which, in connection with the other symptoms, led to a diagnosis of pulmonary edema.

Injections of strychnine and fomentations were without any apparent effect and belladonna was resorted to. A hypodermic injection of 20 minims of a glycerinated tincture was injected, and, no toxic effects having developed at the end of half an hour, a second injection of 15 minims was given. In a half hour the breathing became more quiet and the froth lessened. This improvement was steadily maintained and the man recovered, though the heart is not free from suspicion of dilatation.

The Value of Celluloid in Certain Surgical Procedures.—G. S. Thompson thinks the suitability of celluloid for certain surgical procedures has been overlooked. He employs the celluloid in sheet form as used by photographers for glazing prints. He relates an instance where, after removing the appendix, he inserted between the internal and external oblique muscles a perforated celluloid plate to cure a commencing ventral hernia. Examination six months later showed that the plate had undergone little if any absorption. In a case of inguinal hernia he used two plates one over the other placed in the inguinal canal the cord being passed down a linear cut in the plates to a central ring for its reception so that it passed from the internal ring straight through these barriers and lay on the anterior surface for the rest of its course. In a third case celluloid was successfully used for bridging the gap of a trephine hole. The piece of material was cut to fit the hole firmly and had a small aperture for drainage. Celluloid could be used to replace bone after trephining operations with great advantage in many ways in suitable cases, and perhaps it might be used in plastic operations on the nose to form a rigid basis for the formation of a new nose.

Berliner klinische Wochenschrift, July 18, 1910.

Demonstration of Tubercle Bacilli in Lesions of Lupus Erythematosus.—Arndt, of Prof. Lesser's clinic, refers to the conflict of earlier years on this subject, and incidentally to the failure of bacteriologists to show the presence of Koch's parasite in lesions of this type. Such evidence as exists has been chiefly clinical in character—and refers to the occasional association of erythematous lupus with other so-called tuberculous and paratuberculous lesions and to occasional specific reactions. A case may be made out for the tuberculous nature of certain lesions, based wholly on clinical and experimental findings. The author has devoted the past five years of his activity to this association, apparently because of the numerical frequency of clinical cases of lupus erythematosus in his department. He has made the best of his opportunities in regard to trial sections; and after certain familiar tests had given negative results investigation by the antiformin method gave a positive finding. That is to say, smears stained by the Ziehl-Neelsen method show individual or parallel, slender, slightly curved rods, agreeing morphologically as well as tinctorially with tubercle bacilli. One case is specially described as free from all other lesions and all antecedents of tuberculosis. Aside from the bacilli present, a very marked cutaneous reaction to tuberculin was in evidence. Attempts to find the bacilli in sections had always proved unsuccessful. The use of the antiformin method may be summed up as follows: An excised piece of tissue was comminuted by rubbing up in a sterile mortar, and dissolved in a 20 per cent. solution of antiformin. This solution was centrifugalized and the sediment smeared on 16 new microscopic slides which had been kept in ether and alcohol. The smears were then fixed in the flame. It does not appear that the author has thus far tested many patients by the antiformin method. But two seem to be mentioned, while no less than 175 were tested by the section-staining process. Nevertheless two positive results on a background of previous constant failure enabled him to predict with considerable confidence that the antiformin method must come into general use in all cases where there is suspicion that a very few bacilli may lurk in the tissues.

Treatment of Hysterical Aphonia.—Max Senator refers to the well-worn condition of the status of this subject, of which there is apparently so little chance to make any statements that are new or worth while; but he writes in the interest of Seifert's claim that merely by bending the head strongly backward the patient's voice is restored. When the head is replaced to its normal position the patient again becomes aphonic. The effect is improved if the upper part of the trunk is also bent backward. Investigations upon himself and other healthy subjects showed the difficulty or impossibility of speaking in a faint whisper while in this position. Apparently all the muscles made tense by this attitude cooperate in phonation, so that the latter is, so to say, magnified. The author, however, was unable to corroborate this finding in some of his own patients. In two cases the method of Seifert failed entirely. It is true that one of these was unusually refractory to treatment and was complicated with chronic laryngitis and irregular thickening of the vocal cords. But the other was of a mild type and yielded readily to mild measures after Seifert's maneuver had completely failed. The author also combats Seifert's explanation of the alleged specific procedure, and even the claim that phonation is strengthened by the forced position. Finally he alleges that the patients cannot be thus treated in a laryngological chair, but only in an ordinary low backed chair. As the operator must aid the patient by tilting the chair backward, there is no little danger of an accident.

The Quartz Lamp in Trachoma.—Hegner and Baumm first refer to the use of radiography and radium in trachoma, and the occasional favorable results obtained thereby. The employment of the quartz lamp, borrowed from the dermatologists, on a case of recent trachoma is perhaps the first yet undertaken (at least no prior at-

tempts are mentioned). But two cases are reported. The authors evidently wish merely to place on record the action of the lamp from various points of view. An exposure of from 4 to 10 minutes causes the formation of a false membrane, and a considerably longer one tends to cause general swelling of the eyelids. Mere momentary exposure causes hyperemia. The proper dosage, to be both safe and efficacious, should be that sufficient to produce a thick, false membrane. This should come away in a few days, bringing the follicles with it. From one to three treatments may be required. No cicatrization was produced. If the lids swell they should yield readily to hydrotherapeutics. The authors evidently did not obtain all their information from the two cases cited, for they appear to have tested the lamp quite extensively. The exposure is not very painful and as a rule local anesthesia is not required. The first case was treated 18 months before the report was made, and patient has remained well. The second case is still under treatment. The lamp may be used in combination with other measures.

Münchener medizinische Wochenschrift, July 12 and 19, 1910.

Treatment of Non-Perforating Duodenal Ulcer.—Zum Busch, of the German Hospital in London, would always use gastroenterostomy as the operation of choice. He does not excise the ulcer as a routine measure; in other words, he would use simple suture unless there was a special indication for excision. It is a question whether or not the duodenum, or pylorus respectively, should be closed by suture. This procedure should render the ulcer more prompt to heal and lessen the chances of secondary hemorrhage; but the author apparently dislikes to commit himself to advocating it as a routine measure. He is quite indifferent as to whether an anterior or posterior anastomosis should be made. As a German surgeon practising in England, he notes the frequency of operations for this affection in the latter country in contrast with the policy of nonintervention in Germany, where nonperforating ulcer is perhaps still looked on as a physician's disease. That it has now become a surgical affection is due largely to Moynihan and the Mayo brothers.

The Hypophysis.—Kohn, in a long article on this organ, cautions against the conclusion, so often made in the case of adrenalin, that because some active pharmacodynamic principle may be extracted from an organ, that principle exerts a necessary function in the economy. If we obtain an active principle out of the posterior lobe, and none out of the anterior, are we justified in assuming that the latter has no function; while the former is physiologically important? This claim would be flatly contradicted by evidence otherwise obtainable. We have not obtained our knowledge of the thyroid, adrenals, or other bodies of their kind by the action of their extractive bodies on the economy, but by the methods in use in determining the functions of organs in general. The author concludes that the anterior lobe of the hypophysis is more significant. It contains cells which agree in their characters with certain other active elements in closed glands. The posterior lobe is histologially much less significant.

Spinal Analgesia.—Von Arlt offers considerable evidence to show that untoward results of intraspinal injections are of a character best attributable to mild infection. In other words, we do not take sufficient pains to render the operation aseptic. His argument is based in part on the fact that whatever analgetic is used, the unpleasant collateral effects and sequelæ are invariably of the same character, despite the chemico-pharmacological differences in these substances. Hospital statistics show a steady diminution in percentages of failures and unpleasant results since 1904 (from 11.5 per cent. to less than 1 per cent.) This is due to constantly increasing care in selection of subjects according to a number of standards, together with unremitting efforts to improve the technique with especial regard to asepsis. Five or six hundred operations are done annually under spinal analgesia (at the Brothers of Mercy Hospital, Graz).

Mandelbaum's Reaction in Typhoid Fever.—Kessler has had the following experience with this new diagnostic resource. The method is naturally simple but the bacilli by adhering to the blood corpuscles may simulate clumping. Again if the serum is under-diluted (10 to 15 times) there results inhibition of the clumping and threading. The author would therefore free the serum from red corpuscles and dilute it in the ratio of 1:20 to 1:40. When Eberth's bacillus appears after four hours in the medium, either in clumps or threads, present or past typhoid is indicated; but there is no means of distinguishing between the two from the bacillary arrangement alone. Typhoid may be distinguished from paratyphoid, but not with such certainty as by the Widal reaction. Mandelbaum's method cannot therefore displace the latter, but is worth employing for corroboration. In the text of the article the author also states his belief that the new method adds nothing to our resources for the detection of typhoid carriers.

Köhler's Bone Disease.—Schäffer, of Copenhagen, gives an extremely brief but concise notice of this affection accompanied by a case-history and two radiographs. Köhler's first case was described as recently as 1908, and but few observations are upon record. Patient, a healthy boy of sound stock, was five years old when the affection began. He became listless and depressed, and slept poorly. There was a mild temperature rise. He soon began to limp and complain of lancinating pains in the right foot, the dorsum of which was swollen. The pain was present only on walking. The local symptoms were referred to a slight traumatism—the fall of a brick on the foot. Improvement soon followed, but a radiograph showed a lesion of the scaphoid, which was smaller than normal as if sclerotic. No other lesion was present. The boy, although he had ceased to complain, favored his foot in walking; and in the course of several months the calf of the affected side had become somewhat atrophied. There was some swelling over the scaphoid, but no sensitiveness. Perfect rest for the foot was ordered, the patient being either recumbent or supported by crutches. Under rest, Bier's hyperemia, and massage the condition was arrested; and at a later period (two years), the scaphoid had resumed its natural growth, and the functional result was also perfect. Von Pirquet's cutaneous reaction had given a negative result. The diagnosis was Köhler's disease (although Köhler failed to record atrophy of the calf). The mechanism lay between trauma pure and simple and a developmental defect conditioned by traumatism. Köhler attempted to introduce gonorrhea as a causal factor, but in cases since reported this element could be excluded. The few cases thus far recorded are quite insufficient to permit the drawing of any conclusions as to the nature of the affection.

Gonorrheal Central Corneal Ulcer.—Adam (Prof. V. Michel's clinic) states that the so-called "central corneal ulcer" is in most cases not an ulcer at all, but a necrotic process resulting from thrombosis of the nutrient vessels He reaches this conclusion from having improved his opportunities for histological study of a case of ophthalmoblennorrhea in an adult. Naturally the underlying gonorrhea has to be vigorously combated by the usual means. If a central ulcer develops there is no special indication. This of course does not exhaust the subject, for true gonorrheal ulcers of the maceration type may sometimes occur centrally, although as a rule they are marginal. They are due to purulent stagnation and should be treated with chemical caustics or the electric loop cautery. In general the treatment of corneal ulcer is first preventive—and the preventive technique has been carried to unusual lengths, such as packing the upper conjunctival sac with ointments by the aid of a glass rod. If ulcers form, of either kind or in any portion of the cornea, the principles of treatment are those applicable to corneal ulcer in general.

The Decidual Reaction and Some Peculiarities of the Cervical Mucosa in Pregnancy.—Giorgio Bellerini says that it has become evident that the cervical mucous membrane may often undergo abnormal modifications of a decidual nature. The author instituted systematic examinations of a number of uteri with reference to the possibility of such transformation. The number of patients examined was 32, at various periods of pregnancy. A portion of the mucous membrane was removed from the cervical canal for examination. The histories of the cases are given. He concludes that a decidual reaction is much more frequent than is ordinarily believed. One group of cases showed a diffuse decidual change, an expression of the stimulation of pregnancy without any other clinical or histological element. A second group showed besides the decidual modification slight inflammatory reaction of the mucosa which should be considered as a normal reaction of pregnancy. It can have no diagnostic importance in placenta previa. The stimulation of pregnancy influences the cervical mucosa and induces characteristic modifications, proliferation of the glandular structures, hyperproducion of epithelium, inter and intracellular vacuolar formations of the superficial epithelium, etc.—*Folia Ginecologica.*

(Special Report to the MEDICAL RECORD.)

(*Continued from page 297.*)

SECTION OF MEDICINE.

Thursday, July 28—Third Day.

Treatment of Chronic Constipation.—Dr. J. F. GOODHART in opening this discussion defined constipation as an unnatural delay in the passage of the intestinal contents along the colon. From bismuth observations the average period of the passage of the intestinal contents along the colon only would appear to be some twenty hours from taking the meal; to this must be added for delay in the collecting chamber a variable time, probably in most people three to four hours, more or less, until the call for expulsion came. Constipation thus fell into two groups—constipation of the colon, and constipation of the collecting chamber or rectum. The one was an automatic reflex outside the control of the will; the other was largely aided by voluntary effort, and the trouble came into being when voluntary muscular effort failed. The latter was mostly present in old people, or in women of lax habit who had borne children, and in such as had habitually neglected to form good habits. Constipation of the main tract of the colon is a much more intricate subject; it was in the main a physiological one. Its causes concerned themselves with the neuromuscular apparatus of the intestinal wall and the intestinal contents. The nervous element in the circuit was a dominant one in constipation; nervous vigor and its oscillations; habit; the temperament of the subject; the mental condition, and related thereto all the disturbances of secretion, absorption, excretion, associated as they were with flatulence, pain, and muscular cramp, were also of the utmost importance. The physiology of muscular propulsion of the colon contents was discussed. In regard to peristalsis an attitude of trust should be dominant. When peristalsis was unduly excited it might evince tremendous force. The function of peristalsis was to get round corners, hence the fear of kinks, in the absence of tumor in the abdomen, was largely ungrounded. The quantity or bulk of intestinal contents was of great importance in relation to constipation; to ensure regularity of action the colon must be full or moderately distended. There was absorption of food material from the colon and even from the rectum. The muscle in the wall of the colon was adapted for the slow propulsion of its contents, and in this relation there was risk in many instances of not eating enough. The colon was also an organ of excretion. Treatment was not in every case needed. There were many who should accept a several days interval as normal for them and discard aperients. The doctrine of intestinal autointoxication, as developed of late years, was extreme and physiologically unsound. He deprecated the use of intestinal antiseptics and the surgical treatment of chronic constipation. When treatment was necessary, much was to be gained by common-sense physiology. The obsession of the urgency of a daily stool should be attacked; so also that other, that blocks readily occurred; so also a third, that the colon was a poison bag. Bad habits; irregularity of meals; too little food; the dietetic fad; the curse of pill-hunger, were matters to be met. Instil the need of patience and perseverance; leave the bowels alone by thought and deed to work out their own salvation. Massage, electricity, and enemata were of special value of the sluggish bowel of decadence.

Professor BAÜMLER of Freiburg alluded to the Röntgen screen appearance of the colon after bismuth meals. He also looked upon it as normal that the colon should be full. It was desirable that the sympathetic nervous system should be kept in proper tone, having regard to the motor supply of the intestine and to this end a sufficiency of sleep was necessary. Summing up his experience, he would say to a patient, take sufficient food, a sufficiency of vegetables and exercise enough; sleep enough; take a cold bath in the morning, and do not trouble too much about the bowels.

Sir JAMES SAWYER of Birmingham emphasized the point that the intestinal dejecta contained the substance of excretion of glands as well as food residue. Three canons of treatment were not to leave medicinal treatment to patients, not to prescribe drugs unless it could be cured without drugs, and that drugs when used should be combined with suitable adjuvants. The main causes of constipation were enumerated, each of which he maintained was avoidable. The importance of the formation of habit in defecation was insisted on. Physical uprightness in posture should come before drugs and if they were used along with them. Exercises promoting biliary flow were of value. The best diet in the cure of constipation was a mixed diet. Otherwise a diet full of cellulose was of special service. Among drugs he advocated aloes.

DR. H. D. ROLLESTON thought it was important not to minimize the harmful effects of constipation. The personal equation was no doubt a very important one, yet the significance of autointoxication was great. Harmful absorption from the intestine was a real thing. And the ill-effects of liver disease really depended on autointoxication, as also did much of the arterial degeneration existent in the community. He referred to three causes of constipation, want of tone in the muscular wall of intestine, as in hypothyroidism, in which case he would advocate irrigation; excess of tone, as in spastic constipation, often associated with mucous colitis, in which case belladonna or even opium might be effective; and diminished quantity of fluid or secretion.

DR. NEWTON PITT emphasized the point that the rectum was normally empty and the collection of feces was in the sigmoid, and that in defecation the whole of the descending colon emptied itself. Feces were not so much the remains of food as a formation of the intestinal secretions, epithelium, and mucus, while at least a third consisted of bacteria, and the more constipated a patient was, the fewer the bacteria. The effect of constipation varied much in different individuals. He mentioned one case in his own experience in which the normal was once in six weeks, and that with the maintenance of good health. The person with regular habits were those who suffered most from occasional constipation. He also thought fullness of the colon was of extreme importance and mentioned vaselin or agar agar as efficient purgatives.

MR. ARBUTHNOT LANE said that constipation was the result of intestinal stasis, allowing of a large absorption of toxic substances into the blood. Some concomitants or results of intestinal stasis were kinking of the pylorus, dilatation of the stomach as a result of the former, ulcer of the duodenum and stomach, kinking of the ileum and dilatation of the small intestine, kinking of the splenic and hepatic flexures, ptosis of the transverse colon, and fixation of the sigmoid. Reference was made to bacillary infection of the bile and pancreatic passages. The deleterious organisms of the intestine readily migrated into the urogenital pad, the results of which were very intractable. The aging influence of autointoxication and its influence in lowering general body resistance were alluded to. Among other forms of surgical treatment for the more serious effects of intestinal stasis, division of the ileum and removal of the large intestine were specially mentioned.

DR. A. MANTLE of Harrogate referred to the effect of

chronic constipation in producing mucous colitis and enterospasm. He also thought the question of autointoxication had been unduly minimized. Its influence in producing neurasthenia and vasomotor disorders was dwelt upon. He advocated irrigation of the bowel in mucous colitis, 10 or 12 lavation with sulphur water, followed by massage and an arranged diet.

Dr. A. F. Hertz described his observations on the passage of intestinal contents by bismuth meals and *x*-rays and his views on the types of constipation. Referring to the dietetic treatment of constipation, treatment with massage applied to the part of the colon especially weak, as revealed by the *x*-rays. The smallest amount of aperient necessary to produce a daily evacuation should be employed; if it be desired to produce a soft motion a saline aperient was indicated, as it influenced the large bowel alone. In the presence of severe autointoxication the question of operation might be considered, whether lateral anastomosis or other.

Dr. Wm. Ewart discussed the possible importance of distension of the colon with gas and alluded to the training of the function of strain as bearing on the prevention of constipation.

Dr. G. Herschell mentioned the use of a dose of carmine with a test meal as a means of ascertaining the seat of the constipation, following the dose with an enema if necessary. The rôle of colitis in relation to constipation was discussed. Allusion was made to the use of injection of warm olive oil at night in the treatment of spastic constipation. The sigmoidoscope was of much value in the diagnosis of the causes of constipation.

Dr. Guelpa of Paris sent a communication upholding the importance of autointoxication as a concomitant of constipation.

Dr. Stuart Tidey of Montreux had found that the more gregarious a people were the more was chronic constipation prevalent. He favored the treatment by lavage and operation of different kinds for the severer type of the malady.

Dr. Eason of Edinburgh discussed the treatment of constipation with hormones as regulators of peristaltic movements.

Dr. John Haddon discussed points in the physiology of defecation.

Dr. W. Ewart gave a demonstration on the value of percussion of the vertebræ in diagnosis.

Friday, July 29—Third Day.

The third day of the Section's meeting was occupied with the discussion of original papers. Dr. Wilfred Harris of London read a paper on the treatment of neuralgia and sciatica with injections of strong alcohol or solutions of eucaine in normal saline solution, respectively, into the nerve trunks, in which good results were recorded by the method. The paper was discussed by Dr. D. A. O'Sullivan.

Dr. Laurence Humphry of Cambridge read a paper on a case of aneurysm of the aorta communicating with the superior vena cava, which was discussed by Dr. Morley Fletcher. Dr. Humphry and Dr. W. E. Dixon described a case of acromegaly with hypertrophied heart and other organs, in which new pressor substances were found in the urine. It was discussed by Professor Gosall. A communication on the prophylaxis and treatment of diabetes and other diseases by starvation was made by Dr. G. Guelpa of Paris. It was discussed by Dr. R. W. Philip, the president of the section.

One on the effects of electrical currents on blood pressure was made by Dr. Ettie Sayer, which was discussed by Dr. S. Sloan of Glasgow and Dr. J. Haddon.

Dr. A. C. Jordan read a paper on the Röntgen-ray appearances of thoracic aneurysm, illustrated by lantern slides, which was discussed by Dr. Herbert French.

Dr. Souttar demonstrated an improved and simplified gastroscope with a working model upon which its passage could be practised.

Dr. J. S. Mackintosh read a paper on the evolution of racial types of Europe and its bearing on the racial factor in disease. Dr. W. Carmac Wilkinson read a paper on the tuberculin treatment of pulmonary tuberculosis, which was discussed by Professor Sahli of Berne, Dr. G. A. Heron, Dr. Odell of Torquay, Dr. French, Dr. Garson, Dr. Hamilton, Dr. J. F. H. Dally, and the President.

SECTION OF SURGERY.

Thursday, July 28—Second Day.

Previous to the formal proceedings, an interesting demonstration was given by Dr. Depage of "Instruments for Screwing Bones."

Surgical Treatment of Exophthalmic Goitre.—Professor Theodore Kocher of Berne opened the discussion on this subject. He referred to the latest progress in the surgical treatment of the disease. For one thing, it was now possible to make an earlier diagnosis. He strongly advised that a systematic examination of the blood should be made in every case, and more especially when there was any doubt whether the symptoms were those of an ordinary goitre of a nervous source, or of Graves' disease. As a result of recent investigations certain changes had now been found in the blood, which made a positive diagnosis possible. The leucocytes diminished from 7,000 to 3,000 or less, and this diminution was due to a decrease in the polymorphonuclear cells, the lymphocytes being often increased. These changes in the composition of the blood had now been confirmed by independent researchers, and had great value in the diagnosis, and also in the prognosis of the disease. For instance, when one part of the thyroid had been ligatured and the blood was found to return to normal, then it was known positively that the cure was perfect. It had been asserted that analogous changes were found in the blood in some other diseases, but he had always found certain differences, and he was of opinion that in doubtful cases the blood was really the best guide for accurate diagnosis. Recently all cases of hyperthyrosis had been confused with Graves' disease, but there were physiological cases of hyperthyrosis. If in doubt, it was only necessary to consider the coagulability of the blood. In Graves' disease it was found that the coagulability of the blood was slower than in normal blood, and that the intensity was also less. In myxedema one had just the opposite, so that these points were sufficient to decide. It must not be thought that Graves' disease was the beginning of myxedema. These changes in the blood had now been produced artificially. It was well known that if ordinary goitre was treated with iodine preparations, symptoms of Graves' disease often supervened. The supposed influence of the nervous system on exophthalmic goitre was brought out by the fact that many patients referred their symptoms to a fright. Certainly if Graves' disease was due to an irritation of the sympathetic nervous system, it was good practice to remove such irritation by rest. If one did not like to operate in such cases, then one should tell his patient to do nothing, and should do nothing himself. A suitable diet should be given, and all iodine preparations excluded. Such patients might get much worse at the seaside from the effect of iodine. But in most cases such means of treatment were insufficient, and operation was called for. The influence of the nerves could be cut off by ligature of the vessels to one side of the gland, the ligatures probably including sympathetic nerve fibers, or a partial excision of the gland might be performed. In

all cases the patient should first be examined carefully for signs of organic changes in any organs. He had operated in 469 cases of Graves' disease, in several instances operating more than once on the same patient, with a total mortality of 3 4-10 per cent. At first his cases showed a mortality of 5 per cent., but this year it was only 1 3-10 per cent. To get good statistical results, it was necessary to select cases carefully for operation. He considered an irregular pulse was the worst contraindication to operation, and that nephritis also was of grave import. Many observers were now agreed that operation was invariably followed by improvement, and when physicians realized the great danger of long-standing cases of Graves' disease, they would no longer resist early operation.

Dr. Hector Mackenzie of London said he must congratulate Professor Kocher on the wonderful results of his operations. The symptoms which indicated exophthalmic goitre were closely simulated by those of over-activity of the thyroid gland, but the severity of the symptoms was not always proportional to the size of the gland. In some cases as the patient got worse the gland might get smaller. The relation of the thymus to exophthalmic goitre must not be lost sight of. In many fatal cases the thymus was found to be enlarged—although one exception to this had been noticed at St. Thomas' Hospital, where the gland was atrophied. Enlargement of the bronchial glands, and of lymphatic glands generally, had often been noticed. In fact there was no doubt that the status lymphaticus (generally unsuspected) really underlay many cases of exophthalmic goitre, and that this condition contributed to the great risk of the operation. Although he admitted that hypertrophy and overactivity of the thyroid might produce the disease, he did not expect the removal of the gland, or a part of it, to effect a cure; and he had seen no case to support such a view. He would like to know how many cases Professor Kocher rejected as unsuitable for operation, for the results at St. Thomas' were not encouraging, and inclined him to persevere with medical treatment. He thought that many of the cases operated upon abroad must be very mild ones, and possibly quite suitable for medical treatment. He firmly believed that exophthalmic goitre was a disease for which a medical cure would eventually be found, and even in the serious type of case he considered the risk to life of operation to be too great to make it justifiable.

Dr. Bruce of Toronto paid a tribute of admiration to the pioneer work of Professor Kocher. He considered the question of the choice of anesthetic was very important. Professor Kocher used local anesthesia, but in Canada they did not find it suitable. They preferred not to tell the patient when the operation would be done, and to administer a general anesthetic under the guise of an aromatic inhalation, so as to get rid of psychical excitation. He had operated on 20 cases of exophthalmic goitre without a death, but the next two cases had been fatal; one from pneumonia, and the other was found to have an enlarged thymus gland.

Mr. George Heaton of Birmingham said it was still an open question whether the symptoms of exophthalmic goitre were due solely to a hyperthyroidism, or poisoning of the system by an excess of thyroid internal secretion, or whether they are not rather caused by a perverted action of the gland—an "aberrant" thyroidism. For if the first view were correct, removal of the source of excessive secretion must almost necessarily be followed by a cure of the symptoms; but if they were due to a perverted secretion, cure might not so certainly follow if any portion of the gland were left behind. We must bear in mind in considering the operative risks of Graves' disease that many cases of ordinary parenchymatous and cystic bronchoceles exhibit some symptoms of hyperthyroidism. There were pronounced tachycardia and palpitation in many such cases, and occasionally the nervous symptoms were also present, and some slight degree of exophthalmos. They are often mistaken for cases of true Graves' disease, and in fact were regarded as such by some surgeons. Cases of this nature were very numerous. They did excellently when operated upon. The operative risk was infinitesimal, and a complete cure might be assured. It was the inclusion of these cases by surgeons in their statistical list of operations that has given rise to such divergent views as to the risks and dangers of the operation. At any rate, one cannot help thinking when reading some of the series of operations for Graves' disease by American and Continental surgeons, that a good many of the cases so reported would scarcely be regarded here as cases of true Graves' disease, but rather as cases of ordinary goitre, with some symptoms of hyperthyroidism. Putting aside these cases there remained the large class of cases which all recognized under the name of Graves' or Basedow's disease, with the classical symptoms of goitre, tachycardia, and exophthalmos. That purely medical measures failed in a large number of such cases to arrest the progress of the disease few would gainsay; and we had therefore only to discuss here the surgical question. The whole danger of the operation lay in delay. In the quite early stages of the disease the risk of excision, though greater than in simple goitres, was a comparatively small one, but rapidly became greater as the patient's symptoms increase in severity. When the symptoms had been in existence for a considerably longer period and were slowly progressive, or when, as so frequently happened, the patient relapsed as soon as a strict regimen was relaxed, operation might still be advised. But the risks of the operation, which were now much greater, must be fairly put before the patient, and we were no longer in a position to promise a cure, though we might expect great improvement from it. The third class was the advanced or extremely acute case. These were the ones that the surgeon was most frequently called upon to see. All else had failed, the patient was rapidly going down hill, the tachycardia, restlessness, and nervous symptoms were intense, and diarrhea and vomiting with pyrexia were often present. Here surgery fails miserably. With regard to the operation itself, a general anesthetic was to be preferred, and it did not add to the risk, but rather minimized it. Rapidity of operation, gentle handling of the tumor during extirpation, and free drainage afterwards would lessen the risk of thyroid absorption, and for the first 24 or 48 hours afterwards continuous rectal enemata of a weak solution of sodium phosphate should be administered. This was one of the best means at our command for guarding against the restlessness and cardiac collapse which were apt to follow any operation or traumatism in patients with Graves' disease.

Mr. Robert Campbell of Belfast said that in his experience physicians were more inclined to operative treatment than the surgeons. He considered there were two forms of exophthalmic goitre. The primary acute form, in which there was sudden onset and the disease progressed rapidly; and another form in which the patient had an enlarged thyroid for years and then later develops tachycardia. He preferred ether preceded by morphia as an anesthetic. He had had one case in which a patient improved after a partial thyroidectomy, but relapsed after a visit to the seaside. He thought we required more evidence of the mortality of exophthalmic goitre when not operated on.

Mr. R. Kennedy of Glasgow wished to draw attention to a point he had noticed, viz., that the protrusion of eyeball was less noticeable after excision of half the gland, and on the same side. He had noticed the same effect of excision of cervical sympathetic. He considered a general anesthetic very dangerous in such operations and preferred local anesthesia, obtained by ½ gr. of cocaine in a ½ per cent. solution. The rise of temperature noticed after

such operations was not due to sepsis, but to the absorption of gland substances. In acute cases with heart symptoms, he preferred delay with rest in bed and hygienic treatment.

Mr. Gilbert Barling of Birmingham thought this condition must be considered both from a medical and from a surgical point of view. In regard to Professor Kocher's statement that there is a diminution in the coagulability of the blood in Graves' disease, he remembered a case of his own which died after ligature of the thyroid vessels, and in which there was complete thrombosis of the femoral vessels. In regard to the question of anesthetics, he would like to give his experience of three fatal cases he had met with. In the first, a woman, 35 years of age, with severe and prolonged Graves' disease, after a period of bed and rest, he had ligatured both thyroids under chloroform, and she died the same day. He blamed the chloroform. The second case was also a woman, aged 50. He ligatured both thyroids under eucaine, and she died in three days. Then he did not like local anesthesia. In the third case, a nurse, aged 23, he ligatured both thyroids under ether, preceded by morphine, and she died the same day. He came to the conclusion that the main thing was to operate early, and that the kind of anesthetic did not matter.

Mr. Donald Armour of London said he had abandoned ligaturing in most cases, and preferred excision of the gland. In regard to the anesthetic, he preferred chloroform given by the Vernon Harcourt method, and preceded by morphia and atrophine. He deprecated handling the gland during the operation.

Mr. Deansley of Wolverhampton considered all cases of exophthalmic goiter were one and the same, differing only in degree. He considered that the progress of the disease was arrested by operation, but he had not seen any case cured.

Mr. Walter Spencer of London preferred a very simple operation. He divided the isthmus and widely separated the two parts under gas. This was a useful procedure, if only as a preliminary to subsequent tying of the thyroids.

Observations on Some of the Factors That Determine the Results of Surgical Operations.—Dr. Crile of Cleveland read this paper.

Friday, July 29—Third Day.

Dr. Martel of Paris demonstrated a surgical instrument he had designed for the rapid and safe removal of bone from the vault of the skull.

Conditions Simulating Cancer of the Stomach.—Mr. F. D. Bird of Melbourne read this paper. Syphilis might be mistaken for malignant disease, and when not removed because deemed inoperable might eventually subside. A syphiloma seemed to invite gastrectomy because it was often well defined and situated on the lesser curvature; but the right course was to excise a piece in doubtful cases and examine it microscopically. Syphilitic tumors of the stomach were usually associated with such stigmata as white markings on the liver and scars in the membrane. He cited the case of a man at 35 with a tumor of this kind, which disappeared after four months' antisyphilitic treatment. Wassermann's test should be used before operation. Hydatids and myxedema also stimulated cancer, and exploration by sight and touch was often necessary before a confident diagnosis can be made.

Conditions Which Simulate Cancer of the Stomach.—Mr. Alexis Thomson of Edinburgh read this paper. In 49 resections of the stomach for cancer, microscopical examination, chiefly by the use of large sections, showed that in only 35 was the lesion of a cancerous nature. In 23 specimens from the University Museum catalogued as cancer, microscopical examination showed that only 17 were really cancer. In a total, therefore, of 72 stomachs believed to be cancerous, no less than 20 = 27.7 per cent. were found to be nonmalignant; of these one was tuberculous; the remainder, 19, were instances of diffuse fibromatosis of the submucous coat. The speaker then discussed the characters of fibromatosis, its external resemblance to cancer, and its tendency to be diffused widely throughout the stomach, and to invade adjacent organs—*e.g.* colon and pancreas. It might moreover be associated with chronic ulcer, and fibromatosis with "ulcer-cancer." Fibromatosis was probably of infective or toxic origin.

The Early Diagnosis and Treatment of Cancer of the Stomach.—Mr. Herbert J. Paterson of London held that a definite diagnosis of cancer was not necessary in every case; but only to establish the necessity for surgical treatment. The minimum operation should consist of removal of two-thirds of the stomach with the glands along the lesser curvature, and one inch of the duodenum. In late cases it was advisable to remove the transverse colon and great omentum as well. In most cases it was advisable to operate in two stages: First—Preliminary gastrojejunostomy; second—resection three weeks later. The greater safety of this method more than outweighed its disadvantages. The results of operation, both immediate and remote, were slowly but steadily improving.

Excision of Gastric Ulcers.—Mr. E. Deansley of Wolverhampton read this paper. The results of gastrojejunostomy in these cases were unsatisfactory in the long run, though symptoms were relieved for a time. He advocated removal of nonmalignant ulcers, whether nonperforating or perforating. In support of his views he related his personal experience of eight cases of excision, which convinced him that this should be the operation of choice in all centrally situated ulcers not involving the pylorus or duodenum.

Radical Abdominoperineal Operation for Cancer of the Rectum and of the Pelvic Colon.—Mr. W. Ernest Miles read this paper and submitted tables showing that the steps of progress in extent of operation for rectal cancer, and the period of immunity from recurrence, were steadily increasing. Table VI. set out 26 cases of radical operation in his own practice. He laid stress on preliminary preparation of the patient for one week by clearing out colon, lavage, and use of salol. If stenosis was present cacostomy should be done three weeks before excision. Careful light dieting and the giving of strychnine were advised. The paper was discussed by Mr. Drew, Mr. Bond, and Mr. Mummery, who all gave general support to the measures advocated by Mr. Miles.

The Clinical Manifestations, Diagnosis, and Treatment of Liver Hydatid.—Mr. C. MacLaurin of Sydney read this paper. Jaundice was present in 10 per cent. of the cases. Hydatid thrill was infrequent and of little or no value. Rupture was a serious complication and might follow light injury or muscular action. Most diagnostic tests were not reliable; radiography was one of the best. He recommended transcostal marsupialization at the level of the eighth and ninth ribs, if possible; opening of the sac to be preceded by the injection of formalin.

Suture of the Circumflex Nerve.—Mr. R. Kennedy of Glasgow read notes of a case of suture of the circumflex nerve, eight months after injury. Three defects were found, (1) abduction of arm only 30°; (2) atrophy of deltoid, with absence of response to faradism or galvanism; (3) backward displacement of lower angle of scapula. At operation two bulbous thickenings were found in the circumflex nerve connected by loose connective tissue. The bulbs were excised and the ends of the nerve joined. Good recovery followed after five months. He showed photographs of the patient taken before operation and eighteen months after.

The Operative Treatment of Chronic Mucous and Ulcerative Coitis.—Mr. Lockhart Mummery read this

paper. When medicine had failed, operation should not be unduly postponed. The disease had a high rate of mortality. Widal's test should be used to exclude typhoid; and sigmoidoscopy should not be omitted. Appendicostomy was the operation of choice, followed by regular irrigation.

The proceedings concluded with a vote of thanks to the readers of papers during the three days' session, moved by the President, Sir Victor Horsley, and replied to by Professor Kocher.

SECTION ON GYNECOLOGY AND OBSTETRICS.

Thursday, July 28—Second Day.

Treatment of Fibromyomata Complicating Pregnancy.—Dr. W. H. H. Tate of St. Thomas' Hospital, London, opened this discussion. He said that, in his opinion, there was a tendency to overestimate the dangers by some authorities and to underestimate them by others. He would direct attention to the following points: (1) Changes in the fibroids; (2) the tendency to abortion; (3) the risk in labor. Increase in size of the tumor might cause great distress, and in large fibroids there might be serious symptoms from pressure on the diaphragm. The most danger from pressure occurred when the fibroid was situated in the true pelvic. Torsion of the pedicle during pregnancy was exceedingly rare. The frequency of miscarriage in these cases had been estimated by Kelly at 25 per cent. and by Pinard at 21 per cent., which was not much above the percentage in normal pregnancies; the danger of miscarriage was that there might be great difficulty in removing the placenta and resulting hemorrhage or sepsis. In labor the greatest danger was rupture of the uterus and this was more likely to occur if the complication had not been recognized beforehand. There was also some danger of postpartum hemorrhage, and during the puerperium the fibroid might become extended and present through the os; sloughing then took place. Necrobiotic change in the tumor might follow delivery, and the symptoms then suggested pelvic peritonitis. True suppuration was extremely rare. Only a very small number of cases called for interference during pregnancy, and this was the experience of most authorities. As regarded the treatment of fibroids complicating pregnancy, he would divide the cases into three groups: (1) Fibroids in the pelvis, including cervical tumors; (2) fibroids in the lower uterine segment; (3) fibroids above the brim of the pelvis. In the first group he would push the tumor above the brim, and, if that was impossible, would do an abdominal myomectomy, postponing interference to as near full term as possible; he would not recommend vaginal enucleation in these cases. Fibroids of the second group might interfere with labor, but he advised expectant treatment during pregnancy, and he condemned induction of abortion. Where the fibroid was entirely abdominal most of the cases needed no treatment, but, where operation became necessary, he advised myomectomy. Prophylactic operations for interstitial fibroids had no place during pregnancy, and induction of abortion and of premature labor was universally condemned. The question arose whether myomectomy should be done when other fibroids were present. He thought it was advisable. He strongly advised conservative treatment during pregnancy, because that particular pregnancy might be the woman's only chance of having a child.

Dr. Amand Routh of Charing Cross Hospital, London, agreed in the main with Dr. Tate. He thought it was becoming more fully recognized that surgical treatment was not required during pregnancy. He drew attention to the improvement in results compared with 30 years ago, when women in labor complicated by fibroid almost all died. The softening change which took place during pregnancy favored nature's method of surmounting the difficulty by rendering the tumor more easy to displace. Induction of abortion and premature labor should be entirely given up. If myomectomy was required on account of degenerative changes and other fibroids were present, he would let the case go to as near term as possible and then do a cesarean hysterectomy.

Professor Spencer of University College Hospital, London, said that it had been estimated that of women of 40 years of age 25 per cent. had fibroids, so that pregnancy with fibroids was more common now than formerly, as women were marrying later in life. He had performed myomectomy during pregnancy on one occasion only. He had never removed the pregnant fibroid uterus in the earlier months. He had seen many cases even with large fibroids go through an easy labor. Dr. Tate had mentioned pain as a reason for operating, but he had never seen a case in which operation was required for this symptom, and he found that by putting the patient to bed on a milk diet the pain usually disappeared.

Some Cases of Pregnancy Complicated by Fibromyoma Uteri.—Dr. Cuthbert Lockyer of London read this paper. There had been five cases in which surgical interference was called for during pregnancy. In four of these he had performed abdominal hysterectomy and in one myomectomy. Three cases required operation in the puerperium; in one vaginal hysterectomy was performed, and in two total abdominal hysterectomy. See printed list appended.

Mr. Alban Doran of the Samaritan Hospital, London, advised leaving the cervix and ovaries in all cases in which hysterectomy was performed.

Mr. Christopher Martin of Birmingham had seen two cases of uncontrollable vomiting with interstitial fibroid which had required induction of abortion. In these cases he attributed the vomiting to the presence of the fibroid. He considered myomectomy the operation of choice.

Dr. A. J. Wallace of Liverpool showed a large fibroid tumor which had been attached by an area 4 inches in diameter to the pregnant uterus and which he had removed by myomectomy, without disturbing the pregnancy.

Dr. Nigel Stark of Glasgow had found that large interstitial fibroids were most difficult to deal with, and, in some of these cases, had performed induction of labor, followed later by myomectomy.

Dr. Hubert Roberts of London said that tumors of the upper uterine segment were of no importance in connection with pregnancy. Cervical fibroids were the most dangerous. He did not believe that malpresentations or post partum hemorrhage were more common than in normal cases. He would not operate for pain alone. He would only do panhysterectomy when the uterus was septic.

Dr. Arnold Lea of Manchester had met with 8 cases altogether; 5 cases were operated on during pregnancy, 4 by hysterectomy, 1 by myomectomy. There was red degeneration in four of the cases.

Dr. A. E. Giles of Chelsea Hospital for Women, London, thought that some of the speakers had underestimated the danger and risk of these cases, and he pointed out that when the patients were in a lying-in hospital or under expert supervision the danger was much less than in general practice. He thought that complications occurred in 50 per cent. of the cases. He held that women with fibroids should be advised not to marry. He discountenanced induction of abortion or labor, but advised that patients should be kept under strict observation. When operating for this condition at term by cesarean section he would always do hysterectomy and not subject the woman to the risks of another pregnancy.

Dr. Lloyd Roberts of Manchester said that 50 per cent. of those women miscarried. He had in many cases seen fibroid tumors disappear in the puerperium.

Dr. Walter Swayne of Bristol had dealt with three

cases. In the first there was a large abdominal tumor and dyspnea; he did hysterectomy. In the second he did abdominal myomectomy for a tumor the size of a cocoanut and patient miscarried six weeks later; and in the third he enucleated through postfornix and patient went to term.

Professor Murdock Cameron of Glasgow has never seen fibroids disappear after labor. He sterilized in all cases of cesarean section unless the patient refused permission.

Mr. Furneaux Jordan of Birmingham advised myomectomy in preference to hysterectomy, and he had had two cases in which normal labor had followed myomectomy.

Dr. Tate, in reply, said that there were undoubtedly some cases in which operation was indicated for pain alone.

Two Cases of Occlusion of the Bowels by the Retroverted Uterus.—Professor Gottschalk of Berlin read this paper. The first case was one of acute incarceration of the bowel by the retroverted, fixated, nonpregnant uterus and was cured by a laparotomy. The second case was one of obturated ileus by the retroverted, puerperal uterus causing a pseudopuerperal peritonitis and was cured by the knee-elbow pelvic position.

Localized Necrosis in an Adenomyomatous Right Tube Associated with Left Tubal Mole.—Dr. Frances Ivens of Liverpool reported this case. There was a nodule one-half inch diameter in tube wall. She discussed the theories of formation of adenomyoma including Recklinghausen's and the question of the possibility of the necrosis in her case being due to tubercle.

The Causal Treatment of Dystocia in Cases of Pelvic Contraction.—Professor Von Herff of Basle, who was unable to be present, sent this paper, which was read by the secretary. He said causal treatment could only be effected in two ways: (1) By enlarging the opening of the pelvis; (2) by reducing the size of the fetal head. As regards (1), this could be attained to a slight extent by the hanging leg (Walcher's) position or to a greater degree by section of the pelvis. The maternal mortality of symphyseotomy was 8 per cent. and of pubiotomy 4 per cent. In addition to this, numerous injuries resulted. In some cases the locomotive powers were impaired, in others there was prolapse of the vagina, but the most serious result was permanent incontinence of urine, and he asked should not one case of the latter discredit the operation? The fetal mortality of these operations was 8-9 per cent. The second method of causal treatment by attacking the child could be carried out by: (1) Inducing premature labor. This should never be done more than four weeks before full term. (2) Reduction of size of craniotomy. This should be chosen in all cases when the child was dead. He had not perforated a living child, but he owned that it was not always unavoidable in general practice. He had found that 80-90 per cent. of his cases of induced labor were delivered spontaneously after induction; 20 per cent. of the children died before the end of the second week. This was a greater mortality than after pelvic section, but on the other hand the mother ran no danger, and the maternal mortality was nil. He recommended induction of labor in all cases in which the pelvic contraction was not too great, and he always performed the operation by puncturing the membranes.

Dr. Tate of London thought that there had been a tendency to put induction of labor on one side in favor of the more brilliant operation of cesarean section, and was of opinion that when there was a reasonable chance of getting a living child by induction this operation should be chosen.

Dr. Swayne of Bristol thought contracted pelvis was largely a matter of locality. It was rare in Bristol.

Dr. Buist of Dundee agreed that puncturing the membranes was the best way of inducing labor.

Dr. Mary Scharlieb, President, questioned the influence of diet, as she had often seen large, healthy children born of starved women in times of famine in India.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Thirty-Second Annual Congress held at Washington, D. C., May 3, 4 and 5, 1910.

(Special Report to the Medical Record.)

James E. Logan, M.D., of Kansas City, Mo., President.

First Day, Tuesday, May 3.

President's Address.—Dr. James E. Logan of Kansas City, Mo., in his address paid a tribute to the founders of the Association, reminding his hearers of the unfavorable conditions under which these men began their work. He called attention to the necessity of being careful in regard to the admission of new members. The meeting in Washington every three years was a most admirable feature, as it enabled the members to keep in touch with the progress in other specialties. It had come to be recognized that the two main functions of the nasal cavities and the nasopharyngeal space were respiration and drainage and that nothing must be allowed to interfere with the free and proper performance of these duties. It was, of course, plainly seen that congenital deformities and the traumatisms of childhood as well as accidental injuries in adult life produced conditions rendering respiration imperfect and prohibiting drainage. Hence the rhinologist had ceased merely to spray out nostrils and apply topical remedies and had become a surgeon. Reference was made to the sudden death from accident of Dr. Gordon King of New Orleans, an active Fellow of the Association, and a tribute was paid to his memory.

The Nasal Phenomena of Neurasthenia.—Dr. Charles P. Grayson of Philadelphia said that recent neurology drew a rather sharp line between inherited or essential neurasthenia and that which was acquired or more or less voluntarily assumed and which was indeed scarcely more than symptomatic of an autointoxication which exerted its pernicious effects upon the higher nerve centers. To the rhinologist there was practically little difference between the two. The nasal disorder of neurasthenia was to be differentiated from hay fever. The exciting causes of the former were different from those of the latter and bore no relation to season, animal or vegetable excitants and were relieved by outdoor life, which aggravated hay fever cases. Excitants of the former might be central while those of the latter were peripheral. But in the former the vasoparesis and the infiltrative tumefaction of the turbinates are at times even more accentuated and so complete had been the vascular stasis that the incision of the edematous turbinates had given escape to a quantity of mere bloodstained serum. Such a condition as this might well account for the headache, mental apathy, and even melancholia of neurasthenia. In such cases mere cauterization of the turbinates was insufficient. They should be first drained of their serum by multiple puncture or free scarification followed by the cautery, either chromic acid or galvanic. Internally such tonics as the glycerophosphates of lime and soda in combination with full doses of struchnine should be given.

Dr. B. R. Shurly of Detroit said that he had made during the last year observations on carrier pigeons after making long flights. He made sections of the spinal cord observing under the microscope the action of fatigue, and it was possible to note an absolute change in the finer granulations of the anterior portion of the larger nerve cells. Such a change in the human being would explain the various vasomotor neroses confronting us in neurasthenia. There was also an actual change in the natural secretions. The dryness in the air passages which these neurasthenics often complain of would promptly respond

to regulated doses of sheep's thyroids. Again the exhibition of iodine was often of great value.

Dr. J. Payson Clark of Boston said that no one would feel justified in making a diagnosis of neurasthenia from nasal conditions alone. The more we knew of the latter the more cases would we be able to remove from the category of neurasthenia. In some cases he had found in both antra of Highmore a glairy mass which would come out in one piece and the removal of which rid the patient entirely of local symptoms which were greatly affecting his general health.

Dr. R. C. Myles of New York City had seen such cases as Dr. Grayson described produced by sarcoma of the septum and by various sinus inflammations. In other cases there was an intumescence of the tissues relieved by surgical intervention which did not affect the sinuses. These patients did not stand operation well, and after them often became profoundly depressed. He had seen during the past winter cases of peculiar pains in the neck, thyroid enlargements, excited hearts, etc., in which the dried thyroid had aggravated rather than relieved them.

Dr. H. L. Swain of New Haven thought that there was in some of these neurasthenics some anatomical conditions or physical properties in the mucous membranes differing from those of normal individuals. They had thinner walled vessels, less fibrous connective tissue and fewer muscular elements. Given this lack of firmness in texture of the vessel wall and the hyperesthetic nerve endings and we had ample cause for the condition under consideration. There were many expressions of nerve-tire which was perhaps the real significance of the term neurasthenia.

Dr. Grayson, in closing, said that he would not make a diagnosis of neurasthenia from nasal conditions alone. A large proportion of patients, however, manifested the symptoms he had described. Many of the phenomena might be due to other conditions than neurasthenia. Various toxemias might cause temperature, engorgement, edematous turbinates, etc., but these conditions were transient. In the class of cases described in his paper the symptoms were continuous. They must have been due to something else than toxemia, for they had improved under general treatment while the local condition remained the same.

Some Points in the Comparative Anatomy of the Larynx in the Anthropoidea.—Dr. J. Gordon Wilson of Chicago presented this paper, which was based on studies of the larynges of a Chinaman, orang-outang, several macacus monkeys, and a marmoset. These were compared with the larynges of a Caucasian, adult and infant, a young lion, and some of the domestic animals such as the cat, dog, and horse. In the Chinaman the characteristic features were (1) a pouch behind the arytenoid, and (2) an anterior sinus, both of which are Simian characteristics. In the orang-outang the most distinguishing features of the laryngeal ventricle and its appendages were (1) their union across the middle line anteriorly, (2) the pouch-like cavity posteriorly behind the arytenoid, and (3) the extralaryngeal sacs. In the *Macacus rhesus* the floor of the ventricle was almost level with the edge of the true vocal cord, while the false cord was only slightly if at all excavated except where the appendix came off. Anteriorly the true and false cords approximated near the middle line. No canal or sulcus existed as in the orang-outang. On the other hand the cords of each side were separated by a vertical median furrow which passed up into the entrance of the median sac so that a probe passed up from below entered the sac. In the marmoset the aperture between the true and false cords was a mere slit. The ventricle came anteriorly to within 0.5 mm of middle line. No transverse sulcus connected them. In the Rhesus, however, they were separated by a median longitudinal furrow. At the upper part of the median gutter lay a marked depression suggesting the opening of a median sac, but no trace of one was found on careful dissection. A probe passed up from the ventricle into the appendix reached into a small cavity in the hyoid near the middle line. The body of the hyoid was expanded, being 1 cm broad in the middle line, and indicated the position where both the ventricles met together though they did not fuse. The second portion of the paper indicated the relation of the thyroarytenoid muscle to the vocal cord. In connection with this subject a series of microscopic drawings was presented and the variations traced throughout the series of animals studied. The various theories as to the functions of the laryngeal sacs were thus given; that they acted as resonators, that they poured secretion on the vocal cords and kept them moist (Fraenkel), that they lightened the upper part of the body and assisted them (apes) in climbing (Vrolick), and that they acted as a protection (extra laryngeal sacs in apes) for the vessels of the neck (Denker). The author stated his view that in emotional states these inert sacs could be called into play, could be distended and modified in form. Thus there could be given to vocal emission a tone of peculiar and significant intensity. It appeared to him that the characteristic cry of the howling monkeys was not intended to frighten the animals' enemies as is generally stated but was intended to modify the voice in order to express mental states and emotions. A monkey was capable of uttering some half dozen sounds of different pitch. The howling was most marked during the breeding season. Regarding the appendix, the author discussed its varying size in relation to laryngocele and the lateral extralaryngeal sacs in man. Laryngocele was an enlargement of the appendix which projected beyond the normal limits of this diverticulum, for example into the sinus pyriformis or above the hyoid into the glosso-epiglottic fossa. The extralaryngeal sac was an enlargement of the appendix which projected through the thyrohyoid membrane lateral, the thyrohyoid muscle and lies under the platysma hyoids. There appeared to be sufficient evidence that certain enlargements of the appendix were pathological, *e.g.* the presence of a tumor blocking the aditus laryngis causing a dilatation of the ventricle. But in a general way all were to be classed with hernia due to a congenital or acquired weakening of the thyrohyoid membrane, and as a consequence dilatation subject to respiration. In a comparative study of the musculature directly related to the vocal cord the outstanding facts appeared to the author to be a gradually increasing complexity of the thyroarytenoid muscle and a closer approximation of it to the ligamentum vocale. The facts suggested a function directly related to the true cords and their physiological activity. They showed the development of a mechanism by which a finer or more exact control of the vocal apparatus can be obtained. The incorporation of the muscle in the cord would bring the activities of the cord under the control of the nervous system. If the sacs could be used to vary the voice in states of emotion how much more exact, how much more capable of development, would such a muscular mechanism be?

Exhibition of Anatomical Preparations Demonstrating Communications Between the Blood-Vessels Supplying the Dura, the Orbit and the Nasal Chambers.—Dr. George E. Shambaugh of Chicago exhibited sections illustrating these vessels. He said that these vascular connections could be easily made out in gross dissection except that the vessels of the mucosa of the nasal sinuses and the dura and orbit required the preparation of microscopic sections. When it was shown, however, that the vessels of the dura and orbital periosteum, nasal mucosa and sinus mucosa sent branches to supply the bony plates separating these structures it could be assumed that connection between the two sets of vessels occurred within these plates. The author alluded to the teaching of Zukerkandl and Killian on this subject.

Dr. H. P. Mosher of Boston said that statements on this subject as given in the text books had been vague and indefinite and that it was eminently satisfactory to have the matter definitely settled by such a careful observer as the author.

The Manifestations of Recurrent Influenza of the Nose and Throat.—Dr. J. L. Goodale of Boston said that during the last few years his attention had been attracted to a group of cases exhibiting a well-defined symptom-complex. They had been characterized by a primary involvement in the lymphoid tissue in the pharynx or nasopharynx with an immediate extension of inflammatory phenomena to the mucosa of the sinuses, trachea and bronchi with simultaneous subsidence of the inflammation in the lymphoid tissue. There was a history of annual attacks of gradually lessening mildness. Examination at the onset revealed reddening and swelling of the lymphoid follicles in the pharynx. It was important to note that the involvement of the lymphoid structures preceded any disturbance of the nose or lower air passages. An important feature was the involvement of the ethmoidal sinuses and of a definite region of the bronchi on the affected side. It was also noted that if there was a septal deviation the middle turbinate on the concave side was more frequently involved than its fellow. The question arose what was the pathological link existing between such attacks in the regions which predisposed them to invasion? In the nose we might have chronic hypertrophy or actual polypoid degeneration of the mucosa. In the bronchi there was no direct lesion shown by post-mortem findings. We might have bronchiectasis or hypertrophy of the bronchial mucosa. It would seem, however, that we probably had a state of affairs in a definite area of the bronchi analogous to that of the involved turbinate. Out of a series of twenty cases the author had never been able to abort any of them. Applications of the silver salts to the inflamed pharyngeal granules doubtfully shortened the duration of symptoms while the sinus and bronchial stages were not influenced but came on regularly. It seemed to him that while the symptoms were increasing in intensity, transition to a colder, drier, and higher region did more harm than good. He had come to regard perfect rest at home as the best course in the first half of the affection. After the acute stage was passed and the fever had subsided it seemed as if removal in the winter months to a warmer and moister climate, as Charleston, or the whole coast from South Carolina to Palm Beach, gave little improvement. Patients were no better after their return than before. The interior regions in these same localities manifested a prompt and beneficial effect. A stay of at least two weeks was necessary. A return from these localities to the more stimulating Northern air was often followed by prompt and immediate benefit even though this was not manifest in the South. Local cauterization of perhaps a single follicle in the pharynx was more beneficial to the cough than were sedatives.

Dr. J. E. Newcomb of New York said he could verify from personal experience the statement of the reader of the paper with reference to Southern climates. He had found Deland, Fla., the best and driest climate for those with the sequelæ of grip.

Dr. W. E. Casselberry of Chicago desired to emphasize the good resulting from cauterizing some one follicle or group of follicles in the pharynx. Persistent tickling and irritation were greatly relieved by this procedure. Next in order he would place cleanliness of the secretions. As to climate he had had better results from the dry regions of the west than elsewhere.

Dr. J. E. Logan of Kansas City had been inclined to assign the pharyngeal recesses as the place of entrance of infection in these cases. The application of a thirty per cent. solution of silver nitrate had been successful.

Dr. Goodale had found in his experience with the disease in his own person that crude carbolic acid answered every necessity of a cauterant and preferred it to the silver salt. It was difficult to apply properly medicinal agents to the nasopharynx. The upright arm of the applicator needed to be much longer than was usually the case.

Quinine and Urea Hydrochlorate as a Local Anesthetic.—Dr. E. Fletcher Ingals of Chicago gave his experience with this remedy. For a long time he had been searching for an agent that would produce prolonged anesthesia of the mucosa for the relief of hay fever and hyperesthetic rhinitis. In the treatment of the latter condition he had used this anesthetic many times before making long, deep, linear cauterizations across the inferior turbinate. He combined 15 per cent. of the urea-quinine solution with a 5 per cent. suprarenalin solution of 1-2000. He had used the same solution in the larynx, trachea and bronchi in connection with ether anesthesia in six bronchoscopies in children for the removal of foreign bodies from the lungs without any unpleasant results. It gave excellent results in a painful operation on the ethmoid cells. Here it was injected submucously, diluted about 15 times with topical application in the nares in three or four cases. He had employed it also for turbinectomies, removal of polyps and spurs and for submucous operations. It seemed to him to act much better than did a 20 per cent. solution of cocaine in adrenalin 1-1000. In nasal neuralgia and in one case of hyperesthetic rhinitis it do not seem to do well as it smarted so badly. He had found that ordinarily the healthy nose would bear a 10 per cent. solution. Rubbed up with sugar of milk, a strength of 5 per cent. was as strong as could be borne in a nasal snuff. It was a very valuable anesthetic but the author's experience did not lead him to expect very much from it in either hay fever or hyperesthetic rhinitis, but in view of the claims made for it in producing prolonged anesthesia and in view of the old treatment of hay fever by nasal applications of a solution of quinine he thought it was well worthy of a trial in these affections. The solution turned to a brownish hue after a few hours but seemed to work as well as ever except that the activity of the adrenalin was somewhat diminshed. It was better to combine the solutions just as they were to be used.

Dr. J. Solis-Cohen of Philadelphia had for many years used this remedy in pernicious malarial fever. He had removed growths from the larynx with as much facility as with cocaine. He had also used it in operations in the nasopharynx.

Dr. W. E. Casselberry of Chicago inquired if he had had any experience with it in laryngeal tubercle.

Dr. B. R. Shurly of Detroit had used this remedy in tonsillectomies but its injection had been followed by considerable swelling. He had known of glottic edema following its use.

Dr. J. Gordon Wilson of Chicago said that it was necessary to distinguish between true anesthesia and lack of response on the part of the nerve to a stimulus owing to protoplasmic death.

Dr. J. E. Winslow of Baltimore had for some months done all tonsillectomies under this anesthetic. Injection should be made of a 3 to 5 per cent. solution some fifteen to twenty minutes before operation. He had had no bad results although there was sometimes considerable swelling. With regard to the prolongation of the anesthesia his experience did not bear out that of the statements of various writers.

Dr. H. L. Swain of New Haven said that the protoplasmic death mentioned by Dr. Wilson was a most desirable thing to accomplish in laryngeal tubercle, simply from a humanitarian point of view.

Dr. Solis-Cohen of Philadelphia had had under treatment a severe case of tuberculous ulcer of the larynx and

one application of a 20 per cent. solution of this anesthetic allowed the patient to swallow for two or three days. Anesthesia followed in two or three minutes.

Dr. Ingals, in closing, said he had had as much bleeding with this as with any other anesthetic. He had not injected the tonsils at all. Considerable swelling had followed injection in his own cases. Most of them had prolonged anesthesia. The first few times he had used it in the nose it did not even take down the swelling and the bleeding was so obstinate that he had had to use adrenalin.

Syndrome of Sphenopalatine Ganglion Neurosis.—Dr. Greenfield Sluder of St. Louis said that the anatomical connections of this ganglion gave disease evidence in the motor, sensory, sympathetic, and gustatory fields. In the sensory realm there was a wide and characteristic distribution of pain along definite lines. The neuralgia might appear at the root of the nose, in and about the eye, in the region of the ear, is emphasized at the mastoid, may run to the shoulder blade, and in severe attacks to the axilla, arms, and fingers. There was an accompanying anesthesia of the soft palate and of the pharynx as low down as the bottom of the tonsil, possibly in the lower and anterior part of the nose. Often in the motor field the soft palate was involved; the palatine arch might be lower on the affected side, the uvula was often deflected from the affected side. The palate raphe was deflected in the act of swallowing from the affected side. Gustatory changes were a diminished and delayed taste on the affected side for sweets, salt, and bitters, applied to the middle third of the tongue. Some patients showed a perverted sense of taste while others were accompanied by salivation. Three of the author's cases had great sneezing with profuse serous secretion resembling that seen in rhinitis nervosa. Treatment referred to the use of cocaine to the nasal mucosa which might give immediate relief to some cases and in recent cases of moderate severity the relief was permanent. Sometimes several applications of a strong solution were required. In moderate to severe cases of longer duration, that is up to nine months, injections of alcohol into the ganglion had proved curative. In most cases three injections had been necessary. The application should be made near the sphenopalatine foramen.

Dr. H. P. Mosher of Boston said that he had had during the past year some experience in cauterizing the ganglion in vasomotor cases and in cases of asthma. His experience was summarized as follows: One case of intractable vasomotor rhinitis of years' standing was given a year's relief, and of three cases of asthma one was stopped for a week, one for two weeks and one for two months.

Dr. J. Gordon Wilson of Chicago said that while the changes in vasomotor and secretory functions were suggestive the gustatory phenomena reported by Dr. Sluder were difficult to reconcile with our present accepted knowledge of the course of these fibers. The results of testing the anterior part of the tongue varied so much in healthy individuals that to obtain definite results the test should be made both before and after operation.

Instruments for Direct Intubation of the Larynx.—Dr. Harris P. Mosher of Boston presented the instruments and gave a description of their use.

Dr. J. R. Winslow of Baltimore had had experience with this method which he strongly commended.

Dr. W. K. Simpson of New York City did not think that the method was superior to the old indirect method which he thought enabled one to exert more pressure in cases of stenosis. He would like to know if any one had had experience with the direct method in children?

Dr. J. P. Clark of Boston had had experience with the direct method in a case of diphtheritic stenosis in a child. He had found Dr. Mosher's instrument very useful.

Dr. A. Coolidge, Jr., of Boston thought we were working much less in the dark by the direct method.

Dr. Simpson said that the moment we put the tube in by the direct method we were obscured in our field as much as if we used the mirror.

Exostoses of the Accessory Sinuses.—Dr. H. P. Mosher also exhibited several charts illustrating these lesions and read a short paper on the subject. He said it would seem that the growth of exostoses in this region was analogous as far as size was concerned to the growth of ovarian cysts. The exostoses arose from small structures, had small pedicles, and reached in the end a size much greater than that of the structure from which they sprang. The author's specimens showed them to be equally common in the frontal and sphenoidal sinuses. They might exist either as mamillated regions or a single knob-like projection. In the first form there was a generalized periostitis, in the second form there was a true exostosis. In the phenoidal sinus there were, for the most part, needle-like spines. The author had seen none springing from the floor of the frontal sinus, but from all its other walls. It would seem reasonable to believe that the large knob-like masses seen in the frontal were the result of repeated traumatism. The author had also seen several instances of hemorrhagic sinusitis. It was not hard to conceive of local areas of hemorrhage in the sinus mucosa, the bleeding resulting from rarefaction of the air in the sinus. Given a small hemorrhage in the mucosa its organization and calcification might start an exostosis. In the author's case of frontal sinus exostosis the mass was removed by morcellation, but he was inclined to prefer a burr driven by a dental engine.

Radical Operations on the Maxillary Antrum.—Dr. W. L. Ballenger of Chicago gave the following technical description of a new operation on the maxillary antrum: (1) Incision under cocaine infiltration anesthesia in the vestibule of the nares along the ridge formed by the nasoantral angle. (2) Elevation over the antral wall of the periosteum. (3) Removal of the nasoantral angle with rongeur forceps until the anterior angle of the antral space is opened on a level with the inferior meatus. (4) Removal of the entire nasoantral wall beneath the attachment of the inferior turbinate through the opening at the anterior angle with Wagner forceps; the still further removal of the heavy portion of the mass at the floor of the nose with a small mallet and chisel. An opening was thus made extending from the extreme anterior angle to the posterior extension of the antrum and from the floor of the nose to the attachment of the inferior turbinate. The claims made by the author for this operation were: (1) It was as radical as the Denker operation as it affords complete access to the antrum for curettage, treatment and inspection; and (2) it was a much more conservative operation as it did not injure or remove the inferior turbinal and might be done with much less loss of blood and under local anesthesia in a few minutes.

The Influence of the Automobile Upon the Upper Air Passages.—Dr. D. Bryson Delavan, New York City, read this paper (see page 305).

Dr. B. R. Shurly of Detroit called attention to the development of a new occupation, that of automobile tester. These men were accustomed to ride several hours daily subject to the ill effects of the exhaust pipes all that time. Many of them kept the mouth open during the high-speed periods—developed the so-called automobile face. He had seen a number of cases of wind paralysis occurring in these persons.

Dr. J. O. Roe of Rochester had noted the lessening of sinus diseases in motor car users since the invention of the wind shield.

Dr. W. B. Casselberry of Chicago said that motoring was now so common that it would be hard to find a case of sinus disease in any one who did not use the motor car.

THE POST-OPERATIVE HISTORY OF EIGHTEEN CASES OF MAGNETIC FOREIGN BODIES REMOVED FROM THE EYE BY THE HAAB OR GIANT MAGNET.*

BY CHARLES STEDMAN BULL, A.M., M.D.,

NEW YORK.

THIS paper is intended to apply only to the comparatively small number of cases in which the patients could be followed and the ultimate results tabulated. The great majority of the cases from which the foreign bodies were removed by the Haab magnet disappeared after discharge from the hospital, and could not be traced. Only such cases were considered in which the foreign body was located either in the vitreous or in the fundus.

The particle of iron or steel was successfully located by the *x*-ray apparatus in every case, and a skiagram made.

The foreign body was successful extracted by the Haab magnet in every case but one.

The extraction occurred through the original wound in seven cases, and through another channel in ten cases.

The foreign body was located in the vitreous in eight cases, and in the fundus in ten cases. An iridectomy was done at the time of extraction in seven cases.

A cataract subsequently developed in eight cases. Phthisis Bulbi resulted in six cases, and sympathetic uveitis in eight cases, and an enucleation was necessitated in ten cases.

The vision was permanently lost at the time of the accident in five cases.

There was immediate useful vision after the removal of the foreign body in two cases. Permanent useful vision was not gained in any case.

From a careful examination of these eighteen cases, and of a large number of cases already published by various authors, it would seem that the following points are to be emphasized:

First.—The foreign body should be located and an attempt made for its extraction as soon as possible after the accident, in order to lessen the dangers of infection.

Second.—When the wound of entrance is in the anterior segment of the eye, and the foreign body has been located in the vitreous or fundus, no attempt should be made to draw it forward by the Haab magnet through the wound of entrance. It seems far wiser to make an incision through the sclera at the nearest point to the location of the foreign body, and extract it by means of the small magnet.

*Read before the American Ophthalmological Society at its meeting in Washington, May 3, 1910.

Third.—These eyes are all suffering from the shock of the original accident, and we have not properly appreciated the severity of the second shock of applying the giant magnet, and forcibly drawing the foreign body through delicate tissues already seriously injured.

Fourth.—These eyes are all in a dangerous condition, and the prognosis must always be unfavorable, with the great danger of the development of sympathetic uveitis.

Fifth.—If infection has already begun, the eye should be enucleated at once.

Sixth.—While the prognosis in these cases is always very grave, it is better when the foreign body is lodged in the vitreous than when it is lodged in the retina or ciliary body.

Seventh.—Great care should be exercised in the application of the giant magnet, for more injury may be done by the fragment of iron or steel being drawn through the tissues by the magnet than was caused by the original accident.

Eighth.—If the attempted extraction fail, it is better to enucleate the eye at once.

Ninth.—Even after a successful extraction, useful vision will be permanently lost in the majority of the cases, and enucleation will be necessary in order to save the fellow eye. The danger of sympathetic inflammation is ever present, and a general insidious uveitis may develop months and even years afterwards and extend to the fellow eye.

CASE I.—Male, machinist, aged 38. First seen October 10, 1905. Two days before right eye was struck by piece of steel flying from a lathe. Small wound in sclerocorneal margin, on temporal side; perforation of iris; partial opacity of lens. Skiagraph located the foreign body in fundus, on nasal side of optic disc, and 5.5 mm. below the horizontal plane. Fragment of steel drawn forward by Haab magnet and entangled in iris near wound of entrance. Small incision in limbus in superotemporal quadrant, and fragment removed by Hirschberg magnet. Small iridectomy with free pillars to incision. Atropine and bandage. Three days later signs of purulent panophthalmitis; enucleation on fourth day on account of sympathetic irritation in fellow eye. Size of steel fragment 1 x 2.5 mm.

CASE II.—Male, aged 50, machinist. First seen October 31, 1905. Left eye injured ten days ago by chip flying from hammer. Wound in corneal margin on temporal side, in horizontal meridian. Hole through periphery of iris. Lens cloudy on temporal side. Ophthalmoscope shows what may be the foreign body in the vitreous on the nasal side, and just below the horizontal meridian. Skiagraph locates the fragment in the vitreous about in same locality marked by ophthalmoscope. Steel fragment drawn forward by Haab magnet into anterior chamber, but entangled in the iris opposite wound of entrance. Small iridectomy outward, and fragment of steel removed with iris tissue. Atropine and bandage.

Size of fragment 2 x 3.5 mm. Vision equal to counting fingers. Three months later, phthisis bulbi and V = 0.

Case III.—Male, aged 30, carpenter. First seen November 6, 1905. Right eye injured this morning by a fragment of steel from a chisel. Small wound through center of cornea. Line of opacity through lens. Vitreous very cloudy, probably from intraocular hemorrhage. Fundus invisible. Skiagraph locates foreign body 25 mm. back from cornea and 12 mm. to temporal side. Haab magnet denotes presence of iron, but fails to draw it forward after three attempts. Patient refuses to have any operation done on the eye though told of danger. Probable size of steel fragment 1 x 2 mm. V = 5/200. Was seen once a week for three months. At the end of that time lens was entirely opaque, and there was decided siderosis of the iris. Vision was light perception. Since then the patient has not been seen.

Case IV.—Male, aged 28, machinist. First seen October 12, 1906. Left eye injured by piece of steel sixteen days before. Wound of entrance in ciliary region in superonasal quadrant. Vitreous cloudy and anterior chamber half full of blood. V = counting fingers. Skiagraph locates foreign body in fundus, 5 mm. on temporal side and 6mm. below. Apparent size 1.5 x 3.5 mm. Haab magnet draws fragment into wound of entrance from which it is extracted by forceps. Vitreous filled with blood. General uveitis develops, but not of suppurative type. Three weeks later signs of sympathetic iridocyclitis, and enucleation at once performed. Sympathetic trouble subsided in four weeks under proper treatment with V = 20/30.

Case V.—Male, aged 60, machinist. First seen November 19, 1906. Left eye injured six weeks before by fragment of steel watch spring. Wound in inferotemporal corneal margin. Lens opaque. Iritis with posterior synechiæ. V = light perception. Two skiagrams made and foreign body located in vitreous, 11.5 mm. back and 9.5 mm. above the horizontal. Haab magnet drew the foreign body, after three trials, into anterior chamber, but entangled in iris. Iridectomy in inferotemporal quadrant, and fragment removed by Hirschberg magnet. Clean coloboma made. No reaction. Hot applications, atropine, and bandage. Patient discharged at end of third week with V = light perception. One month later returned with sympathetic iritis in right eye. Immediate enucleation. Ultimate vision in right eye 10/200.

Case VI.—Male, aged 24, carpenter. First seen December 21, 1906. Left eye injured by piece of steel from chisel the day before. Wound near center of cornea and through center of lens. Iris not wounded. Vitreous hazy. Foreign body located by skiagraph in vitreous, 2.5 mm. to nasal side and 8 mm. below. Haab magnet drew fragment of steel into anterior chamber. Corneal incision below and extraction by small magnet. Very little reaction. Eye remained quiet for five days and then panophthalmitis developed. Enucleation two weeks later on account of sympathetic irritation in fellow eye.

Case VII.—Male, aged 20, plumber. First seen February 6, 1907. Right eye injured three days ago by piece of iron flying from a hammer. Wound in ciliary region in inferotemporal quadrant. Prolapse of ciliary processes. Vitreous full of blood. V = light perception. Skiagraph locates foreign body in vitreous, 4 mm. below horizontal and 9 mm. to nasal side. Haab magnet drew fragment or iron to external wound, and it was removed by forceps. Patient discharged on fourteenth day. Lens clear. V = 20/200. Seen at intervals of a week for two months, at which time V = 20/200, but eye still tender in ciliary region. Six months later patient appeared with advanced phthisis bulbi, due to cyclitis.

Case VIII.—Male, aged 30, carpenter. First seen March 18, 1907. Right eye wounded three days before by piece of steel from a wedge. Wound in ciliary region, on temporal side, just above horizontal meridian. Vitreous full of blood. Skiagraph located foreign body in vitreous 8.5 mm. on nasal side and 6 mm. below horizontal. Haab magnet drew fragment into iris but not through it. Incision made with keratome outwards and upwards in limbus, an iridectomy was done and the fragment of steel removed with the iris. Size of fragment 1 x 3 mm. Iridocyclitis began on eighth day, and the eye was enucleated on the twelfth day because of sympathetic irritation. V = light perception.

Case IX.—Male, aged 28, machinist. First seen September 23, 1907. Left eye injured that morning by piece of steel from lathe. Wound in temporal side of sclera, just posterior to sclerocorneal margin. Vitreous full of blood. Skiagraph locates foreign body in fundus, 18 mm. back, and 7.25 mm. above horizontal. Haab magnet fails to dislodge fragment. Wound of entrance enlarged and then small magnet introduced and draws fragment to wound and extracts it. General uveitis and gradual atrophy of eyeball. Enucleation eleven weeks later on account of severe pain. No suppuration or signs of sympathetic trouble. Size of fragment 2.5 x 4 mm.

Case X.—Male, aged 47, carpenter. First seen September 27, 1907. Left eye injured three days before by piece of steel from hammer. Wound in sclerocorneal margin on temporal side. V = counting fingers. Skiagraph locates foreign body in vitreous, 9 mm. back, 2.5 mm. on nasal side, and 2 mm. above. The Haab magnet drew piece of steel into the bottom of anterior chamber from which it was removed through a corneal incision. Size of fragment 5 x 2 mm. Patient discharged on twelfth day, with V = 10/200. Was seen four months later and V. was then same. Has not been seen since.

Case XI.—Male, aged 42, blacksmith. First seen November 18, 1907. Right eye injured by piece of iron from a horseshoe nine weeks before. Iridochorioditis with severe pain. Scar in cornea in inferior quadrant and iris adherent in scar. V-light perception. Skiagraph locates foreign body in fundus, 31 mm. back, 6 mm. above, and 5 mm. to temporal side. On third attempt Haab magnet drew the fragment of iron into anterior chamber. Corneal incision below and extraction by small magnet. Size of fragment 1.75 x 10 mm. Enucleation five days later on account of sympathetic trouble in other eye.

Case XII.—Male, aged 20, plumber. First seen November 20, 1907. Right eye injured two days before by piece of steel from hammer. Wound just above center of cornea. Iris not incarcerated. Skiagraph locates foreign body in the fundus 21 mm. back, 5 mm. on nasal side, and 3 mm. below horizontal. Foreign body drawn into anterior chamber and extracted through corneal incision. Severe iritis followed. Patient discharged at end of third week. Lens cloudy. V = 20/200. Three months later lens entirely opaque but light perception and projection good.

Case XIII.—Male, aged 32, blacksmith. First seen December 11, 1907. Right eye injured ten days ago by piece of steel from hammer. Wound of entrance in ciliary region in infero-temporal quadrant. Vitreous full of blood. Lens cloudy. V = light perception. Skiagraph locates foreign body in fundus, 15.75 mm. back, 2 mm. above and 15 mm. to nasal side. Haab fails to dislodge fragment after three trials. Incision made through sclera at point indicated by skiagraph and after some difficulty the piece of steel, 5 x 1.5 mm., was removed by Hirschberg magnet. General uveitis followed, ending in phthisis bulbi. There were no symptoms of sympathetic trouble.

Case XIV.—Male, aged 40, stevedore. First seen February 24, 1908. Left eye injured one week ago, while removing an iron band from a box. Wound through center of cornea. Lens opaque. Sphincter margin of iris lacerated. No reflex from fundus. Skiagraph locates foreign body in fundus, 20.5 mm. back, 3 mm. on temporal side, and 1.5 mm. above. Haab magnet at first trial drew particle of iron through the iris into the anterior chamber, and it was removed through corneal incision below, and measured 3 x 8 mm. Severe uveitis followed, with loss of light perception, and the eye was enucleated ten days later, on account of sympathetic irritation.

Case XV.—Male, aged 36, machinist. First seen October 2, 1908. Left eye injured two days ago by piece of steel from a hammer. Wound in limbus in infero-temporal quadrant. Iris lacerated at periphery. Blood in anterior chamber and vitreous, 7.5 mm. back, 3.5 mm. to the nasal side, and 1 mm. below horizontal. Haab magnet on second trial withdraws fragment of steel with considerable violence through wound of entrance. Severe pain and reaction. One week later, eye quiet and vitreous cloudy. V = fingers at one foot. This patient was not seen again until February 18, 1909. The left eye was then atrophied, the cornea hazy, the pupil was closed by exudation, there was subnormal tension and no light perception.

Case XVI.—Male, aged 15. First seen October 19, 1908. Left eye injured six weeks before by a fragment of nail. Iridocyclitis and traumatic cataract. Wound of entrance just above corneal center. The skiagraph located foreign body in vitreous, 8 mm. back and 1 mm. to nasal side. The Haab magnet drew it into anterior chamber, from which it was extracted through an incision in the limbus. The uveitis grew worse and on the fourteenth day the right eye showed ciliary injection. Atropine was instilled and the left eye immediately enucleated. The sympathetic irritation disappeared in a week.

Case XVII.—Male, aged 16. First seen February 22, 1909. Right eye injured two days before by piece of steel from a hammer. Wound in limbus in superotemporal quadrant and iris lacerated. Blood in the vitreous. Skiagraph located the foreign body in the fundus, 20.5 mm. back, 2.5 mm. to the temporal side, and 6.5 mm. above the horizontal. The fragment was drawn forward by the Haab magnet till it protruded through the iris at the wound of entrance, and was then removed. Small iridectomy removed the lacerated iris. On sixth day all blood absorbed; wound healed. V = 20/20 with glass correcting the refractive error. Patient insisted on leaving hospital against advice and was not seen again till March 30. There was then a severe iridochoroiditis in the injured and a well-marked uveitis in the other eye. Enucleation of the right eye was refused by the parents. The process of degeneration went on very rapidly and ended in marked phthisis bulbi in both eyes. V = 0.

Case XVIII.—Male, aged 54, machinist. First seen April 6, 1909. Left eye wounded by a piece of steel on March 1. Wound in sclero-corneal margin in the infero-temporal quadrant. V = light perception. Skiagraph located foreign body in the vitreous, which was full of exudation. Steel fragment removed by Haab magnet through wound of entrance. Iridectomy then done and lacerated portion of iris removed. Was discharged from hospital at end of three weeks with V = 10/200. Was last seen on October 4, 1909. The lens was entirely opaque and V = light perception with faulty projection and subnormal tension.

47 West Thirty-sixth Street.

THE IMPORTANCE OF EARLY RECOGNITION OF CANCER.*

By ISAAC LEVIN, M.D.,

NEW YORK.

According to the present state of our knowledge of the pathogenesis of cancer, the malignancy of carcinoma or sarcoma is not due to a specific infection or intoxication of the organism, but to the capacity of the tumor to infiltrate the adjoining healthy tissue, or to disseminate through the blood or lymph channels into distant organs. In either case the danger to the organism consists in the invasion of some vital organ by the tumor cell, and the subsequent interference with the function of the former. If a malignant growth recurs after the removal of the primary tumor, the recurrence always indicates that the removal was only apparently complete.

At the early stage of its growth, a malignant tumor disseminates only in its immediate vicinity, while metastasis in distant parts occurs at a much later period. In other words, a malignant growth is, in its early stages, a strictly local process.

There is ample evidence of this local character of cancer. In a great majority of cases cancer begins only in one place or organ and remains localized for a certain length of time. If a malignant tumor were simply one of the expressions of a general constitutional disease, its simultaneous occurrence in different localities of the same organism would be more frequent. Another clinical evidence of the local character of the early stage of the disease consists in the fact that cancer affects the general health of the patient only at a late period of its development.

The most interesting microscopical proof of this contention is found in the fact that the cells of the metastastic tumor are structurally idenical with the cells of the original growth, no matter where the metastasis occurs. This shows clearly that all the characteristics of malignancy are due to the power of limitless proliferation of the cancer cells developed in the primary focus of the disease.

The recent experimental investigations on the transplantation of carcinoma and sarcoma from one animal into another of the same species also clearly indicates that the disease in the new host begins with the proliferation of the implanted group of cells and that only subsequently these cells disseminate into distant organs and impair the general health of the animal.

*From the Department of Pathology of Columbia University, at the College of Physicians and Surgeons.

But the most convincing evidence of the local origin of cancer is the ever increasing success in the radical cure of the disease by early and complete surgical operation. By the older method, when only the tumor itself was removed, the number of permanent cures was extremely small, and in an overwhelming majority of cases the life of the patient was not perceptibly prolonged by the operation, but, as was stated above, recent pathological research has shown that in all such cases, groups of active cancer cells remained in adjacent tissue and the regional lymph glands. These investigations also indicate the paths through which this dissemination takes place. On the basis of these studies, modern surgery has developed new operative methods by which not only the tumor itself, but the involved neighboring tissue is removed. The results of this method of treatment are most encouraging. Nearly 20 per cent. of the cases of cancer of the stomach are permanently cured, almost as many of cancer of the tongue, over 40 per cent. of the cases of cancer of the breast, and over 50 per cent. of cancer of the uterus. Notwithstanding these great results, the condition of a patient with a malignant tumor is generally regarded as hopeless, even by physicians, who therefore feel justified in resorting to the so-called specific methods of treatment.

In fact, no true specific method for the treatment of cancer exists to-day, notwithstanding the great progress in the modern experimental research of the disease. But modern surgery is capable of effecting a cure in every case of carcinoma or sarcoma, provided the operation is performed in the early stages of the disease—before dissemination into more distant parts of the organism takes place. Our task does not consist so much in proper method of treatment, but in the early recognition of the disease.

The difficulty of diagnosing cancer in the early stages is due to the fact that cancer has practically no specific symptoms. The physicians must bear in mind the possibility of the formation of a malignant growth in every patient of middle age, and must be watchful for symptoms of the disease.

The symptom which is most generally met with in the early stages of cancer is *hemorrhage*. It may be the first symptom in cancer of the nose, mouth, and larynx. In the case of the stomach and intestines, whenever a suspicion of cancer arises, the patient must be watched for this symptom, which may frequently be revealed only on microscopical examination. Bleeding is also one of the very first symptoms in malignant tumors of the kidneys and the bladder. Metrorrhagia, occurring at irregular intervals ,or after an exertion or coitus, is usually the first indication of uterine cancer.

Another symptom by which the beginning of cancer may manifest itself is a *catarrh* of the organ. This symptom may occur in the early stages of cancer of the urethra, nose, larynx, esophagus, stomach, and gall-bladder.

Functional disturbances may indicate the beginning of the disease, as for instance aphony in cancer of the larynx, intestinal obstruction in cancer of the intestines, etc.

Occasionally severe *pain* may be an early indication of the formation of malignant growth. Thus, in cancer of the stomach and the tongue, the pain may be more severe than in any other disease of the same organs.

Whenever any of these symptoms occur in a patient past middle age, the possibility of cancer should be taken into consideration, even when there is no apparent tumor, and a careful investigation should be made by the aid of all the diagnositic methods at our command.

The following is a brief review of the methods most commonly used in making the differential diagnosis of cancer:

1. The microscopical and chemical examination of the secretions. This method is of great value in cancer of the stomach, kidney, bladder, etc.

2. Electric instrumental inspection. This method may be used in cancer of the nose, larynx, esophagus, rectum, and bladder.

3. Exploratory operation. This method is of greatest importance in cancer of the stomach. Whenever a patient past middle age complains somewhat suddenly of indefinite gastric uneasiness, pain, and vomiting, followed by progressive loss of weight and energy and associated with anemia the possibility of cancer of the stomach should be recognized, and in a suspected case, if no improvement takes place in a few weeks at most, an exploratory operation is more than justified. The danger of such an operation, with the present surgical technique, is minimal. The patient is out of bed in a very few days, and if cancer is found, it can be radically removed. The same is true of cancer of the gall bladder, intestines, appendix, etc.

4. Microscopical examination of tissue. The most important diagnostic method consists in the removal of a small piece of the growth and its microscopical examination. This method represents the means for an absolutely certain diagnosis in nearly every case where it may be employed. The method is available for the following conditions:

Cancer of the skin. Any ulcerations, warts, or other similar growths appearing suddenly on the scalp, the face, the lips, or on the surface of the skin generally, in a person past middle age, should be removed under local anesthesia and examined microscopically.

Carcinoma of the tongue. A pipillary outgrowth on the tongue, an indurated nodule, a fissure, or an ulcer of the same organ, calls for a speedy removal of the same tissue for examination. The growth may be radically removed at this early stage, but it very soon invades the adjacent tissue and the lymphatic glands of the neck and then becomes the most intractable of the malignant tumors. The same is true for similar formations occurring on the surface of the mucous membrane of the mouth, palate, pharynx, and tonsils.

Cancer of parotid or submaxillary glands cannot be differentiated in the early stages from syphilis, tuberculosis, or even a purulent infection of the organ. If an unaccountable swelling occurs in these glands, an exploratory incision and the removal of a small portion of the tumor for microscopical examination is very advisable, since these tumors may be radically removed when small, but they grow very rapidly and soon become inoperable. The same holds true for the cancer of the testicle.

Cancer of the larynx in its initial stage resembles so closely an ordinary papilloma that no correct diagnosis can be made on simple laryngoscopic inspection. If a person past middle age is suffering from gradually increasing hoarseness, with or without pain on swallowing, a laryngoscopic examination should be made immediately, and if any new growth is found, it should be removed for microscopical examination.

Cancer of the breast. It is very easy to recognize a fully developed case of carcinoma of the breast, but in its initial stage it may appear as a small tumor in the body of the breast without any retraction of the nipple, which is so characteristic of the disease, and may resemble in all respects a benign adenoma or an inflammatory condition of the gland. Any tumor appearing in the breast of a woman of 40 years of age or more, or a tumor which has remained small for years and then begins to grow rapidly, is very probably a malignant growth, though it may not show any of the characteristic features of the disease. In any of these cases, an exploratory incision and a removal of tissue for microscopical examination should be made.

Cancer of the uterus. This organ presents the most important class of malignant growths, where an early recognition and an early radical operation give excellent results, and where at the same time not only the laity but the profession fail to make an early diagnosis. Any woman who complains of uterine bleeding after climacterium, or even before climacterium, but at irregular intervals, or after exertion, or a woman past climacterium, who notices a sudden onset of leucorrhea with a thin, watery discharge streaked with blood and profuse from the start, should be examined with a speculum. If the cervix is found slightly enlarged and somewhat nodular in character, the tissue appears hard, the mucous membrane paler than normal, or an ulceration is noticed, then a small wedge-shaped piece of tissue should be removed from the cervix and examined microscopically. If no abnormality is found on the cervix, the uterus should be curetted and the tissue fragments examined microscopically. It may appear too emphatic advice to perform even a minor operation on such a slight indication, but one must not forget that the onset of cancer of the uterus is very insidious, that real charactertistic symptoms occur only at a late period, when radical cure is impossible, and that furthermore, the uterus is the most frequent seat of cancer with women. On the other hand, the early recognition of the disease means nearly an absolute chance for a radical cure.

Statistics show that in a great majority of cases cancer occurs in such localities where it is comparatively easy to obtain tissue for microscopical examination, make an early diagnosis, and consequently perform a radical operation with a fair chance of obtaining an absolute cure.

The fact that such an early microscopical examination is made at present in only a small percentage of cases, is not always due to the ignorance of the laity, but frequently also to the neglect of the profession to avail itself of this method of diagnosis.

The George Crocker Cancer Research Fund of Columbia University, as well as the majority of European institutions for cancer research, realize the importance of awakening the profession to the importance of early diagnosis of cancer. In conjunction with the study of clinical statistics of cancer conducted under the auspices of the Crocker Fund, the Department of Pathology of Columbia University at the College of Physicians and Surgeons makes examination of suspected tissue on condition that the attending physician furnish the information needed for the statistical investigation.

ON THE ADAPTATION OF THE HUMAN SALIVA TO DIET.*

By LAFAYETTE B. MENDEL,

with JESSAMINE CHAPMAN and ALICE F. BLOOD.

NEW HAVEN, CONN.

The question of the adaptation of the digestive secretions of the alimentary tract to the work which they are expected to perform has lately been brought into prominence, very largely through the suggestive publications of the Pawlow school. Teleologically such responses on the part of organisms seem most effective and desirable; and it is not difficult to understand how pronounced variations of this type might gradually develop in the course of a long period of evolution. More immediate or sudden adaptations are not so readily comprehensible to the biologist, who looks upon a uniform fixity of structure and chemical function as a fundamental feature or specific characteristic of any species. The assumption of an entirely new chemical rôle on the part of a gland, as the result of a few days of specific feeding, would scarcely be regarded as a biological probability by most physiologists. In accord with this the alleged secretion of starch-digesting saliva in dogs—animals generally recognized as producing non-amylolytic saliva—as the result of a few days' feeding with food rich in carbohydrates has not been substantiated by a number of investigators.[1] One recalls the words of Starling in this connection: "There are riddles enough in physiology without conjuring up a teleological adaptation for which the experimental evi-

dence is inadequate, the conception of its mechanism impossible, and which is not necessary for the well-being of the animal."

Less unlikely than the development of an entirely new type of enzyme in a glandular secretion, where it is normally lacking, is the possibility—as the result of dietary conditions—of a modification in the concentration of a constituent already present. Such considerations are directly related to the practical problem of altering the alimentary functions by the appropriate selection of the food intake. An adaptation of this sort has lately been maintained for human saliva, the secretion most easily accessible for investigation in man. Neilson and Lewis[2] have reported a marked effect of diet on the amylolytic power of saliva. According to them, dietaries rich in protein (meat and eggs) diminish the carbohydrate-digesting power and a carbohydrate-rich diet speedily increases it. In their own words: "Whether this change in the amylolytic power of the saliva due to diet should really be called an adaptation to diet is immaterial. At least there is a change either in the amount of ptyalin or in its activity, or in the concentration of the saliva, which enables more or less starch to be digested with a given quantity of saliva according to the diet. What better name can be given than adaptation?"

0.0064	−	−	−	−	−	−	−	−	−	−	−
0.0040	−	−	−	−	−	−	−	−	−	−	−
$D^{40°}_{30'}$ =	500	500	500	500	500	500	500	500	500	500	500

The somewhat meager data presented by Neilson and Lewis are not entirely convincing; nevertheless we have repeated the general plan of the experiments because of the broader physiological import of the question at issue. Their report need not be reviewed or subjected to criticism here. We desire, however, to emphasize the large number of variable factors which may affect the activity of the saliva independent of the composition of the diet. It is known, for example, that the amylolytic power varies through a considerable range during the day. The composition of the saliva is influenced by the rate and duration of secretion, and by the nature of the stimulus. Saliva collected by dripping from the mouth is not at all comparable in enzyme content with that obtained at nearly the same time by chewing a chemically inert substance. It is, therefore, extremely difficult and absolutely essential to avoid divergencies due to these independent factors, so that the results obtained can be ascribed to broader features of diet per se.

Methods.—Various methods have been employed to measure the comparative amylolytic activity of different specimens of saliva. Nearly all of them involve inherent errors or difficulties. For example, the comparison by estimation of the sugar formed from starch by the same amounts of saliva in a given time necessitates the selection of a suitable period of digestion. It must not be so long that even a small content of enzyme can digest the maximum quantity of starch; nor must it be too short to allow small differences in enzyme concentration to manifest themselves. After numerous trials we have selected the very satisfactory method of Wohlgemuth[3] which measures primarily the concentration of amylase (ptyalin) in the fluid examined. One determines the quantities of (diluted) saliva which are required to convert 5 c.c. of one per cent. soluble starch solution to the point where it just fails to give a blue color when tested with iodine solution. The amylolytic power of the saliva ($D\,40°/30'$) may be expressed by the quantity of such starch solution which 1 c.c. of the secretion is calculated thus to convert at 40° in 30 minutes. The extremes found by Wohlgemuth were $D\,40°/60' = 125$ and $D\,40°/60' = 780$

D.

Saliva (collected by chewing)	Protein Period			Carbohydrate Period							Normal Diet					
c.c.	3/3	3/4	3/5	3/6	3/8	3/9	3/10	3/11	3/12	3/13	3/15	3/16	3/17	3/18	3/19	3/23
0.100	+	+	+	+	+	+	+	+	+	+	+	+	+	+	+	+
0.064	+	+	+	+	+	+	+	−	+	+	+	−	−	−	+	−
0.040	−	−	−	−	+	−	−	−	−	−	−	−	−	−	−	−
0.025	−	−	−	−	−	−	−	−	−	−	−	−	−	−	−	−
$D^{40°}_{30'}$ =	78	78	78	78	125	78	78	50	78	78	78	50	50	50	78	50

Collection of Saliva.—The saliva was collected by two methods: (*a*) by chewing soft paraffin; (*b*) by allowing it to drip from the mouth without any oral stimulation. The amylase content is not necessarily alike in the two "types" of saliva. Wherever comparisons are made, therefore, it is highly important to employ the same mode of collecting the secretion. Furthermore, since it is well known that the enzyme content varies widely in the individual throughout the day—a fact which we can confirm—we have collected the samples to be compared at the same hour, and approximately the same time, after a light breakfast, at 9 A. M.

$D^{40°}_{30'}$ =	200	200	125	125	125	200	200	125?	125	125	781	312	312	312	312	312	500	.....	.....	500

Dietary Routine.—Individuals were thus tested in the same way daily for a period of seven to ten days on their usual (mixed) diet in order to learn the extent of individual and daily variations. In a subsequent period (protein period) no starchy foods were eaten, the dietary being restricted to meat, eggs, cheese, and milk. In the carbohydrate period the diet consisted of bread, rice, vegetables, and fruit. The longest special period included seven days—a time within which Neilson's adaptations were observed to occur.

Protocols.—In summarizing the observations made, we have employed the scheme of Wohlgemuth. In accordance with this the successive quantities of saliva tested stand in a geometrical series, each volume differing from the next by the constant factor 1.6. Owing to the differences in the subjects, the preliminary dilution of the saliva was not alike in all; but the absolute amounts of undiluted secretion used are given in the tables. The designation + represents digestion beyond the beginning erythrodextrin stage as already explained. Concordant duplicate analyses of each sample were made in every case.

$D^{40°}_{30'}$ =	50	50	50	125	....	78	78	125	50	125

G.

c.c.										
0.040	+	+	+	+	+	+	+	+	+	+
0.025	−	+	+	+	−	+	−	+	−	+
0.016	−	+	−	+	−	−	−	−	−	−
0.010	−	−	−	−	−	−	−	−	−	−
Volume (c.c.) in 15 minutes	....	....	....	18 2	17.5	18.0	9.0	11 1	12.0	11.5
$D^{40°}_{30'}$ =	125	312	200	312	125	200	125	200	125	200

We cannot interpret these protocols as evidence of a specific amylolytic adaptation of the saliva to the diet under the conditions selected and made comparable (as far as could be determined) with those reported by the adherents of the adaptation theory. Subject D, with a comparatively weak saliva ($D\,40°/30' = 78$), might especially be expected to have shown an adaptation improvement if any arose. In the nearest approach to an apparent adaptative response by which an increased amylolytic power followed carbohydrate feeding (Subject E), it will be noted that the enzyme content was as marked after three days of fasting as during the diet periods. In the same individual (Subject B) at a subsequent period the amylolytic power was lower during the abundant carbohydrate feeding. The saliva of a well-known vegetarian (H.F.) collected by both methods was examined and, strangely enough, found to be no more active than that of most individuals examined by us. This was true of another vegetarian (C.S.)

Carlson and Crittenden[4] have asserted that the saliva which is secreted fastest exhibits the greatest digestive power. For comparison we have recorded a few data on the volume of saliva collected by the drip method in 15 minutes, together with determinations of its amylolytic power, in protocols F and G.

In the course of his studies on salivary amylase Wohlgemuth[5] has published this statement: "In so far as I can judge at present, the nature of the dietary is without influence on the quantity of ferment. In most cases just as much diastase was secreted in the saliva after meat feeding, as after a bread diet." (p. 12.) Carlson and Crittenden[5], who have anticipated us in similar experiments and far more extensive tests on animals, conclude that "there is no evidence that the ptyalin concentration in the parotid or the mixed saliva is appreciably increased in man, even after years in which meats are excluded and carbohydrates greatly increased." Our own experience leads to a similar conclusion.

THE CHEMISTRY OF THE URINE IN PULMONARY TUBERCULOSIS.

WITH OBSERVATIONS ON THE BLOOD.

By ROSCOE W. KING,

LAS ANIMAS, COLORADO.

In view of the prodigious amount of work that has been done, and is being done, to facilitate accurate and early diagnosis in pulmonary tuberculosis it seems more than passing strange that the chemistry of the urine in this disease should have been so quietly, so constantly, and so uniformly neglected.

The extreme paucity of literature on the subject, together with its elementary, unsatisfactory, and contradictory character renders a review at once unnecessary and unprofitable. None of the authors whom I have been able to consult so much as mention the chemical examination of the urine as a possible aid either in the diagnosis or prognosis of pulmonary tuberculosis; and by more than one we are silently left to infer, if not told with hasty assurance, that in uncomplicated cases the urine presents no evidence of being other than normal.

From purely theoretical considerations it occurred to me that the urine—of advanced cases at least—should reveal two prominent features of the disease, *i.e.* (1) wasting, and (2) an imperfect interchange of gases due to diseased lung tissue. Naturally it was expected that the former feature would be shown by the urea excretion, and the latter by the elimination of the purin bodies. Having convinced myself that significant changes of this character were constantly present and easily discernible in the urine of practically all cases in which the disease had made marked progress it was not unreasonable to assume that similar, if less extensive, manifestations should be detectable during the earlier and less obvious stages of the disease. For evident reasons only cases, with two or three exceptions, were selected which show the presence of tubercle bacilli in the sputum. Out of the 52 cases tabulated below only 9, or 17.3 per cent., are bed patients.

The remaining 43 represent varying stages of the disease. In the majority of instances the examination of the urine was made within a few days after the arrival of the patient in the hospital.

Volume, Specific Gravity, and Color.—The volume of urine excreted in 24 hours is perhaps diminished in the majority of cases of tuberculosis, but this feature is so variable and inconstant as to be of no practical value. Polyuria seems to be met with much less frequently among the tuberculous than apparently normal individuals. It is not at all unusual to find men seemingly in perfect health who excrete more than 3000 c.c. of urine during the twenty-four hours. Victims of active tuberculosis seldom do this. Diminution in the volume of urine, if actually present, may be, and probably is, due to causes entirely apart from the disease.

The specific gravity[1] apparently undergoes no appreciable changes. It is, however, unusual to find tuberculous patients whose urine shows a urinometer reading above 28.0. This is very well shown as follows:

	Total Number	Urinometer Reading		Percentage	
		27 or Over	28 or Over	27 or Over	28 or Over
Patients...	52	3	1	5.8	1.9
Controls...	25	5	5	20.0	20.0

These changes are, of course, due to accompanying conditions and not to the disease. It is well enough, however, to know that 24-hour specimens of urine from tuberculous patients seldom show urinometer readings above 27 or 28, for it is not at all uncommon to find urinometer readings of this kind among normal individuals.

The color of urine is best observed by looking down through a column formed by filling to the mark a 100 c.c. tall form Nessler's jar. Under normal conditions—urinometer reading less than 27—the color should be perfectly yellow. In practically all cases of advanced, and advancing, tuberculosis the color will vary from a slight to a decided reddish tint; and, as a rule, the more emphatic the tint the more serious is the condition of the patient. This red color is no doubt due to the presence of unoxidized pigment resulting from the rapid destruction of red blood cells. These red tinted urines are usually associated with a positive A, or B factor (see below), due, in all probability, to the excessive and pathological disintegration of the leucocytes. Under these conditions the prognosis is unfavorable in the majority of instances. If the volume of urine is less than 2000 c.c. and the color is a bright yellow the indications are that the patient is not in a serious condition. These remarks are applicable to the greater number, but not necessarily all, of the cases of uncomplicated pulmonary tuberculosis.

This table is introduced as showing that the changes which occur in the urine in tuberculosis are not of a qualitative, quantitative, or obvious character. The data included under the heading "Per cent." certainly presents no startling departures from the normal. And it was, perhaps, from information of this kind that certain well known authors were led to state that a chemical examination of the urine in tuberculosis revealed nothing abnormal. The slight diminution in the percent. of chlorin might, in nearly every case, be attributed to the character of the diet as well as to the general condition of the patient, provided, of course, that the character of the diet was an unknown factor.

It has been repeatedly stated, in a vague sort of way, that an absolute increase in the uric acid (purin bodies) occurred in tuberculosis, but such, seemingly, is not the case. The changes which apparently indicate an altered and pathological nitrogenous metabolism are relative rather than absolute. These relative changes are shown in Table III.

The numbers in the column on the left correspond to those in a similar position in Tables I and III. These factors are called diet factors because they reveal, to the experienced eye, the character of diet most largely used by the patient during the time the urine was collected.

It could hardly be intelligently expected that the urine of all cases of tuberculosis would give a positive, or that of all normal people would give a negative, reaction based on relative changes in the normal constituents of the urine unless there was some restriction as to the character of the diet. To

say that all my cases were on mixed diet means little or nothing. Some of them apparently eat a great deal of meat and practically no bread at all. Others are inclined to be vegetarians. Some drink considerable milk. Others, it seems, drink none. The mere fact that they all have access to the same diet does not mean that they all eat the same, or even approximately the same, character of food. It undoubtedly would have increased the value of my work if a uniform diet had been adopted and adhered to. In this way a normal could easily have been ascertained and departures more readily, more uniformly, and perhaps more reliably detected. The fact, however, that alterations are observable in the majority of tuberculous patients with practically unlimited diet variation renders it all the more probable that were the conditions more scientifically regulated the results would have been more pronounced, and of much greater significance.

In taking up the subject of the chemistry of the urine in tuberculosis with patients living on an unregulated mixed diet I hardly expected to meet with the results shown in Table III. My intention was merely to determine whether it would likely be worth while to adopt a certain uniform diet and place the patient on it for forty-eight hours. The urine collected during the last twenty-four hours would have been more suitable for scientific research.

It will probably be suspected, and is possibly true, that some of my positive reactions among the patients, as well as some of the negative reactions among the controls, are due to the character of the diet rather than to the presence or absence of tuberculosis. Still, if it were a demonstrable fact that tuberculous people usually, and normal people seldom, ate shredded wheat biscuits for breakfast, then the eating of shredded wheat biscuits for breakfast would be a valuable, even if it were not a scientific, symptom of tuberculosis. Then, too, the fact that all advanced cases give a very decided reaction would indicate, quite unmistakably, that tuberculosis is capable of producing a relative increase in the principal products of nitrogenous metabolism, and the assumption is well founded that practically all the positive urine, and U-blood reactions among the patients, if not among the controls, is due to this disease.

This table of diet factors was compiled chiefly with the expectation that it would be possible, and necessary or desirable to make some alterations in the essential factors (Table III) under certain dietetic conditions. It seems more than probable that with a much greater number of urinalyses these alterations could be scientifically determined. With the limited data available I have ventured to make only such slight changes as would suggest themselves to the casual observer at all familiar with the influence of different diets on the chemistry of the urine. These changes are embodied in the rules given in connection with Table III.

It is, of course, obvious that some of the factors shown in the table could never occur except under pathological conditions. This is seen especially pronounced in Nos. 12, 20, 26, and 43. Aside from these, and a few similar changes, the information conveyed by the diet factors is of no importance other than to indicate the character of the diet, and in this way to add to or detract from the value of a positive or negative reaction as shown by the essential factors A, B, and C (Table III).

The V-G factor shown in the column on the left is obtained by multiplying the volume of urine expressed in hundred c.c. by the urinometer reading. This factor, like the total solids of urine, gives information of considerable value. Normally it should not be less than 300. Usually it exceeds 325. The influence of tuberculosis on this factor is shown as follows:

	Total Number	V-G less than 300	Per Cent.
Patients	53	32	60.3
Controls	24	2	8.8

Low values of the V-G factor merely indicate that the patient is not taking sufficient nourishment to sustain the body in a state of health.

Reaction A.[4]—This is a purin body reaction obtained by multiplying the per cent. of the purin bodies by 34 and dividing the urinometer reading

by the product. If the quotient is less than X factor A is said to be positive, and the reaction is expressed by deducting the positive value of the factor from X. X = 10 except when the volume of urine is greater than 2,500 c.c., in which case X = 9. There is no room for controversy regarding the value and significance of this reaction. As a rule it is never absent in far advanced cases of tuberculosis; and its presence is due, in all probability, to (1) pathological hematolysis, or (2) diminished oxidation due to diseased lung tissue. It is, of course, probable that both causes operate to produce the reaction. My own experience coincides with that of all available authorities in that normal urine will probably never show a relative increase in the per cent. of the purin bodies sufficiently marked to produce a positive A-reaction. The positive reaction shown among the controls (No. 20) was obtained from the urine of a man who has been employed at this hospital for over two years.

Reaction B.—This is also a purin body reaction. It is obtained by dividing the per cent. of urea by 34 times the per cent. of the purin bodies. The factor has a positive value when less than Y. The reaction is obtained by deducting the value of the positive factor from Y. Y = 10, except when the urinometer reading is greater than the total urea plus the total P_2O_5 eliminated in twenty-four hours —the urea and P_2O_5 being expressed in grams. In these cases Y = 11.[5]

A positive B-reaction accompanied by a positive C-reaction is said to be real. Otherwise it is apparent. An apparent B-reaction is made real as follows: Assuming the C-factor (see below) to be expressed by the first three figures on the left, *i.e.* 156 instead of 15.65, etc., then the last two figures will show the per cent. by which the positive-apparent B-reaction must be reduced in order to obtain the real reaction. Thus suppose a specimen of urine shows a urinometer reading of 20; contains 1.56 per cent. of urea, and gives a positive-apparent B-reaction of 3.00. We divide the urinometer reading by the per cent. of urea until three figures are contained in the quotient. We discard the first figure (always a 1) and use the remaining two, or 28 in the present case, as showing the per cent. the apparent reaction must be reduced. In the case under consideration we should have 3.00 — 0.84 = 2.16—the apparent reaction being 3.00 and the real reaction 2.16. It is unnecessary to make this correction unless the positive-apparent B-reaction exceeds 1.00. A positive B-reaction has about the same significance as a positive A-reaction. They are, in reality, the same reaction under altered dietetic—and other—conditions.

It should be observed that in cases of tuberculosis with a low V-G factor and a marked C-reaction (see No. 43) the B-reaction is apt to be absent owing to the increased value of the C-factor. In such cases, as shown in No. 43, we have a negative B-reaction due to the rapid decline of the patient. In this instance the patient lived less than a week. By considerable alterations in diet even a far advanced case of tuberculosis might be made to give a negative A, or a negative B, reaction, but from my limited experience I think it very improbable that any far advanced case will be found which will give both A and B negative. A positive B-reaction will seldom, or never, be obtained from normal urine.

Reaction C.—This is the urea reaction, and, under reasonable dietetic conditions, indicates the existence of excessive and pathological nitrogenous metabolism. When positive it points to the probable fact that the patient is excreting more urea than can be accounted for in the food consumed. This excess of urea can have only one source, *i.e.* the tissues of the body. These are being more rapidly destroyed than repaired, and if this condition continues the termination must inevitably be disastrous. The value of this factor is found by dividing the urinometer reading by the per cent. of urea. If less than Z the value is positive and the reaction is expressed by deducting the value of the positive factor from Z. This factor can be more readily altered by an unnormal diet than either A or B, and for this reason more caution should be exercised in arriving at conclusions.

Only two of the controls in Table III give a

positive C-reaction. In both cases the men have been on duty in this hospital for more than two years. Z = 9 except in the following instances in which it has a value of 10: (a) The P_2O_5 divided by the purin bodies exceeds 4.00. (b) The urinometer reading divided by the per cent. of P_2O_5 exceeds 150. (c) The total chlorin plus the total P_2O_5 is less than 7.5 grams and the chlorin divided by the P_2O_5 is greater than 2.00. My own experience—coinciding with that of all available authorities—is that the urine of a normal person on a normal mixed diet will rarely show a per cent. of urea much greater than the urinometer reading, and will not, of course, give a positive C-reaction. Only the entire twenty-four-hour specimen of urine should be used for this test, and unless it is known that the specimen is of this kind judgment should be suspended regarding the C-reaction until a known twenty-four-hour specimen of urine is obtained.[9]

Total U-reaction.—This column as well as that showing the least urine factor (L U F) requires no explanation. It should be remarked, however, that when the total reaction exceeds 4.00 the prognosis is probably hopelessly unfavorable. If the total U-reaction exceeds 4.00 and the V-G factor is less than 250 the probabilities are even that the patient will not live thirty days. If, however, the general nutrition factor (G N F) is not PCX (see below) the patient will probably live two or three months, or even longer. It should also be regarded as a less unfavorable indication if the volume of urine (in c.c.) divided by the urinometer reading is greater than 60.

TABLE IV[10]

(1) W.c. over 15,000 and not over 18,000.
(2) W.c. over 12,000 and not over 15,000.
(3) W.c. over 10,000 and not over 12,000.
(4) W.c. over 9,000 and not over 10,000.
(5) W.c. over 8,000 and not over 9,000.
(6) White count under 8,000.
(7) Under 4,000 polys per c.cm.

X cases are those showing tubercle bacilli in sputum.
— cases are those not showing tubercle bacilli in sputum.

Average per cent of polys in over 300 X cases 69.76
Average per cent of polys in over 125 — cases. 60.10

B-U-reaction.—The blood-urine reaction is obtained by dividing the per cent. of polymorphonuclears revealed by a differential blood count by the least urine factor. Normally it will rarely exceed 6, while in tuberculosis it will seldom be less than 6.

TABLE III[9]

Table Showing the Normal Value of the Different Urine Reactions as Computed from the Data given by Various Authors

Authority	A Reaction	B Reaction	C Reaction	Total U Reaction
Parkes.....	Negative —6.0	Negative —7.6	Negative —0.55	Negative 14 10
Yvon and Berlioz..	Negative —3.23	Negative —2.60	Negative —1.46	Negative 7.29
Thudichum.....	Negative —6.0	Negative —7.6	Negative —1.00	Negative —14 6
King.....	Negative —1.8	Negative —1.25	Negative —1.00	Negative —4.05
Heitzmann.....	Negative	Negative —3 23	Negative —1.00	Negative about —7.00
Purdy.....	Negative	Negative —3.23	Negative —1.00	Negative about —7.00

The average normal value is about 5.25. The average in tuberculosis will exceed 7. Hence, if the value of this factor is greater than 6 the B-U-reaction is said to be positive. The following table is of interest in this connection:

The presence of tubercle bacilli in the genuine sputum is, of course, infallible evidence of the existence of tuberculosis. The meaning attaching to the absence of these organisms will vary according to the character of the sputum, and the number of the negative examinations. If the microscopic appearance of the sputum reveals the characteristics of a mouth specimen—*i.e.* large bucal epithelial cells, and many blue staining cocci and bacilli[6], the absence of tubercle bacilli means simply nothing. On the other hand, if the specimens are macroscopically and microscopically satisfactory and tubercle bacilli are not found after five or ten careful examinations the probabilities are great that the organisms are (*a*) absent or (*b*) present in such small numbers as to elude the microscope. The (*a*) probability very likely predominates.[8]

It is, of course, easily understandable how a patient may give ten negative sputum examinations in June, 1910, and then give positive results in January, 1911. There is a time in the history of every case of tuberculosis when the examination of the sputum will fail to show tubercle bacilli. There are reasons to believe that a well determined absence of tubercle bacilli in the sputum affords some evidence of the absence of a moderately advanced, active, and progressing stage of pulmonary tuberculosis, and Table IV is interesting as showing that in all suspected cases of tuberculosis the average per cent. of polymorphonuclears is considerably increased by the conditions accompanying the presence of tubercle bacilli in the sputum.

The table also imparts the following information:

Group.—Under this heading is grouped the 425 cases comprising the table. The arrangement of the groups has been adopted as a matter of convenience.

Group N.—The white count multiplied by the per cent. of polymorphonuclears is less than 4,000. As shown by the first line from top, this group will contain about 3 per cent. of all the suspected cases of tuberculosis, and as shown by line two and three, tubercle bacilli will not be found in the sputum of any member of the group. Line six shows that the average per cent. of polymorhphonuclears for Group N is 46.6. It should be remembered that a far advanced case of tuberculosis might possibly be found in this group, but the per cent. of polymorphonuclears will almost certainly exceed 50, and the B-U-reaction will not likely be less than 8.0.

Group A.—This group includes all patients whose white count is under 8,000. The first line shows that 4.7 per cent. of all the suspected cases belong to this group, and of these the second and third lines show that tubercle bacilli will be found in the majority, or 68.7 per cent. of the cases. The fifth line shows that the average per cent. of polymorphonuclears is 67.8 for the positive cases, and the sixth line shows 61.2 per cent. for the negative cases. The seventh line shows that 63.6 per cent. of all the positive cases will show more than 65 per cent. of polymorphonuclears, while 60 per cent. (line 8) of the negative cases also show more than 65 per cent. of polymorphonuclears. The ninth and tenth lines show that 37.5 per cent of the positive, and 40 per cent. of the negative cases give less than 65 per cent. of polymorpho-

nuclears. In a similar way the data may be drawn from the different groups. Thus, line 7 shows that tubercle bacilli were never found in the sputum of any member of Group B whose blood contains less than 65 per cent. of polymorphonuclears.

In the above remarks I mean by a suspected case one who is about to be surveyed as with tuberculosis, regardless of the presence or absence of tubercle bacilli in the sputum. By a negative case is meant one in whose sputum tubercle bacilli will not be found. This table was compiled chiefly for my own edification and personal use. It is published as being of general interest.

The column in Table III headed G N F shows what may be called a general nutrition factor. It it marked negative when the total chlorin is more than 6.5 grams, and the total P_2O_5 is greater than 2.00 grams. If the chlorin is less than 6.5 and the P_2O_5 is greater than 2.00 we have CX. If the chlorin is greater than 6.5 and the P_2O_5 is less than 2.00 we have PX. If both are less than the assigned value we have PCX. CX or PX alone may occasionally, though not frequently, be due to abnormalities of diet. PCX is practically always an indication of diminished nutrition due to disease. A high total U-reaction accompanied by a PCX nutrition factor is a much more serious indication than the same reaction having only a PX or CX nutrition factor. No. 2, shown in the table, has already survived his urinalysis by about two months, while Nos. 9, 41 and 42 died within two months after the recorded urinalyses were made. The last three columns showing the results of the reactions require no explanation. The B-U-reaction was not determined for several of the controls, and in these cases the absence of record is indicated by three dots.

The essential facts brought out in Table III are, summarily, as follows:

	Per Cent. Showing Positive U-reaction	Per Cent. Showing Positive B-U-reaction	Per Cent. Showing T. B. in Sputum
Patients..	95.60	97.80	95.60
Controls.....	10.00	0	0

The two controls who gave positive U-reactions have been on duty in this hospital for more than two years, during which time they have been more or less intimately associated with the patients. In the absence of a physical examination or a series of sputum examinations it would hardly be reasonable to assume that they are free from tuberculosis. Nevertheless, they were selected as controls because their general physical appearance, etc., suggested that they were probably not tuberculous. The fact that a differential blood count gives No. 6 a B-U-reaction of less than 5.00 and also places him in Group N (Table IV) is almost conclusive evidence that tubercle bacilli would not have been found in his sputum. The B-U-reaction was, unfortunately, not determined on the other control who gave a positive U-reaction. Should his U-reaction have been accompanied by a positive B-U-reaction the indications would have strongly suggested, in his particular case at least, tuberculosis.

The determination of the purin bodies in urines No. 20 and 26 was made by one unfamiliar with chemical methods, and the discrepancy noticed in the total U-reactions, and in the case of No. 20 the B-U-reaction, is almost certainly due to an error. There is little doubt that the B-U-reaction would have been greater than 10.0 in the case of No. 20, had the purin bodies been accurately determined by one capable of doing such work. Of the patients included in this table all were confined to bed with uncomplicated tuberculosis and 60 per cent. of them died within two months after the urinalysis was made. Those dying within sixty days were Nos. 12, 20, 26, 41, and 42. Of the remaining 3 neither will probably live for six months.

The following are the U and U-B reactions given by the bed patients whose urines are recorded in Table III:

TABLE IIIa

Table III No.	Total U-reaction	B-U-reaction	Least U-factor
2	7.69	10.80	A
9	6.14	11.30	A
12	7.64	12.22	A
17	5.50	12.14	B
20	1.26	8.34	A
26	1.97	10.10	C
41	6.06	11.28	B
42	5.36	11.08	B
43	4.81	12.00	C

The writer is fully aware that the data upon which this paper is based is far too limited to warrant dogmatic conclusions, and the statements made concerning the value of the reactions shown above should be regarded as prophetic and probable rather than as scientific and certain. That the suggestions given will prove of value from a prognostic standpoint there is hardly room for intelligent doubt; but that a chemical examination of the urine may be found of unexpected value in the diagnosis of tuberculosis can neither be affirmed nor denied until my own work has been multiplied and confirmed by others.

In conclusion: the chemical examinations of the urine as shown in the above tables was made, with two or three partial exceptions, by the writer personally. Much care was used, and the results are accurately expressed. I have used original and as yet unpublished methods for determining the urea, chlorids, and purin bodies, and there is no reason to expect that my results will be uniformly confirmed unless the same methods are used by others. The use of a ureometer for estimating the urea is of course to be condemned. The methods in vogue for determining the purin bodies are either (*a*) totally unreliable or (*b*) annoyingly tedious.

If a chemical examination of the urine is to be of any value it is essential that an approximately representative 24-hour specimen should be obtained, and in order that such may be, as nearly as possible, the case with patients living on a great variety of mixed diets, the following rules should be adopted and adhered to: (1) Discard all positive A and C reactions as worthless when the urinometer reading exceeds 27. (2) Discard as worthless all negative A and C reactions when the urinometer reading exceeds 22 and the total chlorin exceeds 10 grams. (3) Discard the specimen of urine as spurious when the volume is less than 1000 c.c., or the V-G-factor less than 250 and the patient is not in an obviously bad physical condition. (*a*) Such specimens are certainly spurious when the urinometer reading plus 2 is greater than the total urea expressed in grams. This applies only to patients who are not in a decidedly bad physical condition. (*b*) A volume of urine of 1000 c.c. or less which shows a urinometer reading greater than 27.5 or 28 is discarded as being either spurious or showing an unnormal diet and metabolism not due to tuberculosis. Remember

that only far advanced and hopeless cases of tuberculosis will excrete less than 1000 c.c. of urine during the twenty-four hours, and that in these cases the urinometer reading will probably never exceed 25. This is a rule to which exceptions, if they exist, must be extremely rare.

The twenty-four-hour specimen of urine from tuberculous patients who are nearing a fatal termination will usually, if not always: (*a*) measure between 600 and 800 c.c.; (*b*) have a decided red color; (*c*) show a total U-reaction greater than 4.00; (*d*) show a decided A-reaction (probably greater than 1.00); (*e*) give a B-U-reaction not much less than 10; (*f*) show a urinometer reading between 20 and 25.

REFERENCES.

1. The specific gravity must be accurately determined. A Westphal balance is preferable, but sufficiently accurate results may be obtained by using two urinometers—the one being graduated from 1000 to 1020, and the other from 1020 to 1040. These instruments are usually intended for use at an inconvenient temperature, *i.e.* 15.5° C., and it will be necessary to either cool the urine to this temperature, or, what is preferable, correct for the higher temperature by adding 1 degree to the urinometer reading for every 4 degrees about 15° C. which the urine shows. The temperature of the urine should be taken with an accurate thermometer and the bulb of the instrument must not be allowed to come in contact with the sides of the vessel containing the urine. In the present article the expression urinometer reading (UR) is used instead of specific gravity. The urinometer reading is found by removing the 10 to the left from the figures expressing the specific gravity. Of the figures showing the urinometer reading the two to the left are regarded as whole numbers. Others as decimals.

2. In this table, and as elsewhere in the present article, P_2O_5 Cl, and PB. or Pb., are used for phosphoric anhydride, chlorin, and purin bodies. In the above table U is used as an abbreviation for the per cent. of urea. All the factors in the table are found from the per cent. of the different substances contained in the urine. Thus UR divided by P_2O_5 means the quotient obtained by dividing the urinometer reading by the per cent. of P_2O_5, etc. The per cent. is also used for the numerators in the fractions shown in columns 5, 6, 7, 8 and 9. In all instances the urine is that of an adult male between the age of 19 and 45.

3. The rules laid down at the end of this article should be adhered to in obtaining the different factors and reactions shown in this table. In the table X is used for + or positive. When not otherwise recorded the "Reaction," "Results," etc., are negative. Thus the absence of X in the column S means that tubercle bacilli were not found in the sputum.

4. The word reaction is improperly used, but it affords a convenient means of avoiding tautological or circumlocutory reiteration.

5. The value of Y is increased to 11 only when by so doing a negative reaction is made positive. If the B-reaction is positive when Y = 10, the value of Y remains constant.

6. The method I have most largely used for decolorizing and counterstaining preparations for tubercle bacilli during the last year or so does not, as a rule, show the presence of the uninteresting blue staining bacteria. The presence of the large epithelial cells, however, reveals the source of the specimen. The method is: Dissolve 2.5 grams of anilin blue (W) in one liter of alcohol containing 3.0 per cent. of hydrochloric acid. The specimens are stained with fuchsin in the usual way and decolorized and counterstained with the blue-acid-alcohol. The decolorizing and counterstaining being done by applying the blue alcohol in the same way as the usual acid alcohol. The only difference is that in one case we get a perfectly blue preparation, whereas in the other a colorless film is sought. This method saves time and is perfectly reliable. It is especially desirable for feces, as it eliminates the large number of confusing blue-staining bacteria.

7. In this table, and in Tables II and III, the first and greater series of numbers refer to patients. The second and smaller series to the controls who were selected as probably not being tuberculous. In addition to the data tabulated a qualitative examination was made for albumin, and a quantitative determination made of acetone, ammonia, amidoacids, and in some cases an approximate determination of the starch splitting enzymes. The tables give only such information as is regarded of value for the purpose of the present article.

8. The facts established by this table do much to refute the opinion, or presumption, that many cases of clinical tuberculosis are produced by an acid non-resisting form—or stage—of the tubercle bacillus. These acid non-resisting bacilli are usually accredited with being at least as virulent as the better known acid-fast variety, and it is difficult to understand why the presence of the acid-fast organisms in the sputum should be accompanied by a relative increase in the polymorphonuclears, which is decidedly greater, on an average, than is found in the cases whose sputa contain the equally virulent, but less acid-resisting, form of the bacilli. Take Group B, for instance, and notice that the polymorphonuclears were greater than 65 per cent. in every case, showing the presence of the acid-fast organism. On the other hand, in about 82 per cent. of all the cases which could have been attributed to the presence of acid non-resisting organisms the per cent. of polymorphonuclears was less than 65. In an emergency one might assume that these acid semi-resisting bacilli are also semi-virulent, but our knowledge of the virulence of cultured bacilli showing temporary acid non-fast tendencies does not warrant such an assumption. Again, if the growing organisms undergo the same changes in the lung tissue as they do on artificial media, it would be reasonable to expect that many acid-fast bacilli would always be encountered, since it is quite impossible to obtain and keep, for even a short time, cultures of tubercle bacilli which show no acid-fast organisms. In view of these facts it would seem that the solution of the mystery must lie in another direction.

10. It should be stated that the blood counts here tabulated were made, as a rule, immediately after the arrival of the patients in this hospital, and while the differential counts would, in all probability, be quite different with patients who have been in this altitude and climate for months, it is hardly thought that the comparative results shown in the table would be altered. There is no doubt that the climate and altitude in which this hospital is situated produces a marked increase in the number (per cent.) of lymphocytic cells, with, of course, a corresponding diminution of the polymorphonuclears. Furthermore, it seems very probable that an enzyme contained within the lymphocyte—lymphocytase—is detrimental to Koch's bacillus, and that any treatment, climatic or otherwise, which increases the percentage of lymphocytes will prove beneficial in tuberculosis. Possibly the benefits derived from tuberculin, lecithin, etc., may be partially, if not entirely, explained by the lymphocytosis which follows their administration. Our text-books are a unit in stating that the average per cent. of mononucleated cells (lymphocytes, large mononuclears, and transitionals) in the blood of healthy adults is about 35. I have recently examined a considerable number of specimens of normal blood and am forced to conclude that, in this locality, the average per cent. of the mononucleated cells will hardly fall below 45 or 50. As a matter of fact it is unusual to find less than 40 per cent. of mononuclears in the blood of the supposedly healthy adults connected with this institution. The writer is convinced that the hematology of tuberculosis is sadly in need of an overhauling but he also realizes that this is neither the time nor place to approach the subject. However, it seems advisable to suggest that laboratory workers in different parts of the country should determine for themselves what constitutes a normal differential blood count for their locality. Until this precaution is taken the hematology of tuberculosis and other diseases will remain in its present chaotic condition.

U. S. Naval Hospital.

THE SIMPLE EXTRACTION OF CATARACT.

By JUAN SANTOS FERNANDEZ, M.D.,

HAVANA.

Cataract operation is always a new subject, because it is the most valuable agent that ophthalmic surgery has. In spite of the simplicity reached in its performance, since the time when Daviel lifted it from obscurity to the present date, it offers interesting points of study. The two principal stages of the operation, keratotomy and discission, could be reduced to one: keratotomy and discission with the knife; but that procedure leads us to serious reflections and provokes contradictory judgments.

While almost everybody is convinced that the incision in keratotomy should be superior, and that it ought to occupy slightly less than half of the cornea, many have thought it more convenient to terminate the incision before the periphery is reached. Some have, however, carried it to the periphery, but have neglected the conjunctival flap, a point on which we lay great importance. The keratotomy then made with the purpose of making the discission of the anterior capsule of the lens with the end of De Graefe's knife, is worthy of some study. It has been thought that this procedure had the only advantage of showing the operator's ability in that he could make the extraction at one time and with only one instrument, De Graefe's or some other knife. It is evident that those who practise this method are few. We have known only Cervera of Madrid, who has used it since 1850, before local anesthesia was known, with excellent results, and in more modern times Trousseau of Paris.

In order that the discission with the knife should offer no obstacles to the later steps of the operation, the first stage of keratotomy, that of introducing the knife, should be begun at the corneoconjunctival junction or limbus; but the knife should be so inclined to the transparent cornea as not to have it parallel to the iris or close to it. In this way, when the end of the knife reaches the pupil, it can be directed against the capsule without touching the inner border of the iris; then, after the discission is performed, the counter puncture is made in the same way as the first stage so as to complete the incision without touching the upper edge of the iris.

When the anterior capsule is hard, resists the point of the knife, and is raised with it, it is enough

to move the point of the knife towards the sharpened side, when the resistance ceases and the knife can go ahead to perform the counterpuncture, without any danger of touching the external border of the iris. After the puncture, the discission, and the counterpuncture with the knife, the conjunctival flap must be made, and after it comes the delivery of the lens. Sometimes after the latter, we have found an undue lowering of the internal tension which we have attributed to cocaine when more than 3 or 4 drops of a 3 to 4 per cent. solution was used. In some cases this phenomenon appears when no more than 3 or 4 drops have been used, in others even if very large doses of cocaine are instilled the phenomenon is not produced. This means that there must be some predisposition in the patient. This accident is contradictory to the power attributed to cocaine of provoking glaucoma. When it is observed for the first time it is alarming, especially when after pressing with the fingers or with the spoon the eyeball becomes sunken; but the lens is slowly delivered and the eye regains its normal appearance within a short time, all except the cornea which remains depressed for some minutes, although larger, in due course it recovers its proper shape.

When one thinks that vitreous prolapse is the most serious complication of a cataract extraction, and that the result if the accident occurs before the delivery of the lens, would necessarily be fatal to the eye, it occurs to us that the production of such a collapse of the sclera would be of value in bulging, myopic, almost exophthalmic eyes, in preventing the dreaded escape of the vitreous. We shall never forget a case we saw in Paris in 1891. A noted and distinguished master was operating before a large number of foreign physicians who admired his ability and dexterity. After he had made several simple extractions the next case was that of a priest, not over 45 years old, and of sane and robust aspect. He had protruding eyes. After the keratotomy was performed such a large vitreous proplapse occurred that the operator limited himself to bandaging the patient's eye.

We have not had cases of internal hemorrhage immediately after the delivery of the lens, accidents which are fatal to sight because due to an atheromatous condition of the eye vessels; but in one female patient operated upon for cataract who four months before had an iridectomy performed, in order to enable a successful extraction, there was a hemorrhage, two or three hours after the operation, which destroyed the eye. This was due to restlessness on the part of the patient who thought it would do no harm to go to the table for some soup. The patient ascribed her hemorrhage to the fact that the soup was very hot. The accident was really due to the fact that she did not think it necessary to be quiet, for she thought that the preventive or previous iridectomy which had been performed rendered her immune to any accident. After some time we operated on the other eye by simple extraction only. Under extra vigilance she regained vision without any untoward accident, in spite of a myopia of six diopters.

After the keratotomy and discission are performed and after the lens has been delivered with more or less rapidity it might be considered that all the dangers were past. This is not so, however. There still remains the hard problem of removing all cortical remains. Even operating upon a perfectly mature cataract, there may be some remains left. If the cataract is not mature there may remain inside some remains of the still transparent lens, which later on may become infiltrated and dangerous. This should be prevented by all means, for the secondary cataract may increase the internal tension of the eye and produce synechia or hernia of the iris, or even may cause iritis in diathetic patients, etc.

We always have considered the irrigation of the anterior chamber to be liable to cause serious disturbances. Recently Valude, at the Naples Congress, has associated with corneal suture, the irrigation of the anterior chamber, considering the suture of the cornea as a guarantee to the irrigation; we do not deny its benefits in avoiding the hernia of the iris, or at least opening of the lips of the incision and the anterior synechia. We trust, however, more in the conjunctival flap than in any other single aid.

In this respect practice has taught us that it is better to deliver any cortical remains by pressure through the lids or directly against the cornea by means of the spoon; but should any remnants be left and should we find the day after the operation that the pupil is occluded with them, we would not regret having omitted the irrigation of the anterior chamber, for the reason that if there be but little trauma the eye absorbs the contents very rapidly, as we have observed innumerable times. The important thing is to avoid the opening of the corneal incision by the remnants of the cataract, which act as a foreign body. To avoid this complication we do not have recourse to the corneal suture in all of the operations, because we do not know whether a secondary cataract will occur or not. It is enough for us to make the conjunctival flap as extensive as possible. By this precaution we have been able to observe that in some cases in which the pupil was clouded with cortical remnants, they later have disappeared within 40 days. One of these cases that left the clinic on the fifth day after the operation regained perfect vision. We are convinced that the conjuncival flap after it adheres is far superior to the corneal suture. We also must acknowledge the extreme absorbent power of an eye that has been subject to traumatisms, for more than once we have observed very striking examples of this. We remember a case which we have cited before on account of its originality. It was the case of an engineer whose cataracts were not mature, but on account of his business he could not afford to be completely blind. We were sure that in spite of all precautions there might have been some remnants left, and on that account we performed an iridectomy. At that time we had not beocme convinced of the advantages of the conjunctival flap and the iridectomy was made to prevent a hernia of the iris. In spite of the repugnance we have always felt toward iridectomy in the combined extraction, which we believe to be of greater danger than the simple extraction, we did not regret having done it in this case. On the third day after the operation the eye had a normal aspect, but the family was alarmed because the patient could not see. We noticed a large amount of a dry pulverulent substance deposited on the posterior capsule. It consisted of almost one-half of the remains of the cataract. The patient did not experience any uncomfortable sensation. We were afraid that such a large amount of cortical remains could not be absorbed. We also felt afraid that the posterior cristaloid might remain opaque. All our apprehensions were unfounded, for two months after all the remains had been absorbed and the eye had regained perfect vision.

We will not make this work unduly long by mentioning some other steps connected with the operation. We will refer now to the question of dressing and bandages used in ophthalmic surgery. Ever since our first steps in ophthalmology we have thought it unnecessary to have the dressings put on during forty or more days, and in 1884 we wrote* upon the subject, confirming some previous papers upon that subject. We have established the fact that the eye bandage is not absolutely necessary.

The eyelid is sufficient to guard the incision during the first twenty-four hours (or more) that are needed for the complete coadaptation of the edges of the wound; but this can only be done with very intelligent and obedient patients. We have only dared to follow this method with one patient. A general in the army, accustomed to rigid discipline, remained in a darkened chamber, sitting on a chair for twenty days without opening the eyes. It is necessary to have the lids closed during the first few hours in order to avoid the movements of the eye operated upon, which otherwise are unavoidable. But how is this obtained in the majority of cases, many of them, in spite of having had the bandage removed temporarily in order to ascertain if they could see, as they have confessed to us after they were cured.

In order to diminish the time that the dressing is kept on, the corneal suture is thought of. In the last few years we have become convinced that the same results could be obtained by the use of the conjunctival flap and the disadvantages of the corneal suture could then be avoided. If on the second day the conjunctival flap is already adherent, the dressing can be removed without any fear even if the anterior chamber is filled with cortical remains.

The opened eye is in a physiological condition, and the functions can better be carried out. The conjunctiva recovers its normal aspect.

If the adherence of the flap is synchronous with the disappearance of photophobia, the absence of the dressing is more justified still. Orange yellow glasses can then be used. It is unnecessary to state that the fact of taking off the dressing and bandages does not imply discontinuing of the general care, and the most exact vigilance as in the case of any other eye affection: rest, avoidance of very much light, of dust, and wind, and of any other cause of irritation which are avoided by healthy people.

In conclusion, the simple extraction of a cataract is a very easy operation, thanks to the progress of anesthesia and antisepsis, and the results, we believe, are always beneficial if all the precautions that we recommend after a long practice are taken.

Crónica Medico-Quirúrgica de la Habana, Vol. XI, page 541.

THE CAR BARN BANDITS.

A BRIEF STUDY IN DEGENERACY.

By G. FRANK LYDSTON, M.D.,

CHICAGO, ILL.,

PROFESSOR OF GENITO-URINARY SURGERY, MEDICAL DEPARTMENT, STATE UNIVERSITY OF ILLINOIS.

In my book, "The Diseases of Society and Degeneracy," I have presented what I believe to be the most authentic study yet published of the three criminals known as the Car Barn Bandits, who were hanged in Chicago some years since for murder in connection with the robbery of the "pay" funds of the Chicago Street Railway Company at the south side car barns. The subsequent flight and capture of the murderers after a desperate rifle and revolver battle with officers of the law is a matter of history, the details of which are unnecessary here.

Since the execution of the men, whom I will designate as V., N. and M., I have had the opportunity of observing the remaining members of the various families, with interesting and pertinent results.

V., who was twenty-two years of age at the time of his execution, was of especial interest to me, as I had known his father quite well as a member of various insurance society organizations, and in the days of my general practice had professionally attended various members of the family. I recall at this writing having attended another of the three children, a sister, when quite young, in an attack of convulsions. The boy, V., I did not attend, but I recall that he was said at that time to be subject to epileptic fits—probably, I should infer, not true epilepsy, but epileptoid, as in later life he was not subject to such seizures. V.'s mother was and is a most admirable woman with a family history free of neuropathic taint. Since the execution of her son she has been doing reform work among juvenile criminals, and has become a fairly good practical sociologist.

The father's side of the house would appear to be the important feature of V.'s family history. V., Senior, was a "good fellow," physically well made, but of the unsteady, vacillating type. He was not vicious, though high tempered and easily led by evil influences. He was a pretty good sort of citizen until the age of about forty, when he fell under the spell of a woman of dissolute character, and defalcated for a considerable amount. He was arrested and placed under heavy bonds, which he promptly "jumped," fleeing to Mexico with the woman in the case. His wife has since seen him in Mexico, the woman being still with him.

V.'s paternal ancestry was distinctly neuropathic—traditionally for many generations. The paternal grandfather died of tuberculosis. The paternal grandmother died insane. One paternal uncle was violently insane and died in an asylum fire. Two of V.'s cousins on the father's side have each two epileptic and feeble-minded children. One paternal aunt is, or was, in an asylum for the feeble-minded. A younger brother is a cripple from tuberculosis of the hip. The sister, to whom I have already alluded, was at last accounts in an institution for the epileptic and feeble-minded.

V. favored the paternal side of the house. He was always hot tempered, and as a child had the reputation of a willingness to fight even grown men who chanced to incur his displeasure. Brick throwing at those who displeased him kept his family in hot water a large part of the time. Notwithstanding these defects, V. became an industrious lad, whose dominant idea after his father's downfall was to obtain money to buy comforts for his mother and sister. There is evidence to show that this idea was uppermost in his mind when N., the "plotter" of the trio of desperadoes, showed him the way to acquire money easily. He was of rather an emotional mentality and during his confinement to jail after the murder, professed religion and wrote a quantity of verse which, although crude, displayed considerable sentimental exaltation.

Young V. met his death with a fair degree of composure. As to how much religious exaltation had to do with his quality of gameness I would not venture an opinion.

N., the acknowledged leader of the trio of bandits, was of the "rat" type of criminal. His reputation as a bold and desperate man was entirely undeserved. He was a cunning leader, who was quite successful in swaying characters intrinsically braver and stronger than his own. His bluster and brag, however, deceived the police and press into the belief that he was the premier desperado of the group. I fancy that he nearly succeeded in convincing himself that he was a desperately courageous man, and that he tried to live up to his swaggering pretentions. He attempted suicide after his conviction, and died on the gallows like an arrant coward. It was necessary to carry him bodily to the scaffold and to hold him in a chair until the drop fell.

At the time my book was written, I had no evidence of degenerate heredity to submit in the case of N. Since that time, however, several interesting points have developed. N.'s father has since died insane, and his mother has been arrested twelve or more times for disorderly conduct due to mental derangement. Mrs. N.'s brother has also developed senile dementia.*

M., the remaining member of the trio of bandits, was, in my opinion, the strongest character of the three. He certainly was as game a man as I have ever seen die on the scaffold. In reporting M.'s case I recorded the death of his father while serving a twenty-year term in the penitentiary for rape. His sister has since died insane. His brother also became insane, and was sent to an asylum. He was afterwards discharged as cured, but soon thereafter shot himself.

I made a careful study of the crania of the bandits after their execution and found that their cranial development harmonized fairly well with their degenerate history. Briefly, frontal development was defective in all, especially in M. An odd feature of the men's skulls was the marked flattening of the occiput, asserted by Franz Joseph Gall so many years ago to be the typic feature of criminal crania.

In M. there were some special features of degeneracy. The jaws were markedly assymetric and the palatal arch badly developed and saddle-shaped.

A point which I endeavored to make in reporting these cases in my "Diseases of Society" was that the responsibility of such criminal acts as the car barn murders really lay at the door of society. A pertinent fact in this connection is that the authorities had an opportunity to save the criminals and the lives of those whom they murdered, and to protect society from their depredations, to say nothing of avoiding the expense of the legal machinery necessary to their apprehension, trial and execution. Some years before the car barn murders, the three boys broke into a schoolhouse and dismantled the stationary engine. V. was evidently inspired by the universal deviltry of strenuous boyhood. M. and N., however, took rather a practical view of the escapade. They appropriated and sold the brass fittings of the engine, were apprehended and arrested. V., it seems, was not known in the matter, but with loyalty to his boy companions uppermost in his mind, left his place of employment and went to the neighborhood of the police station in which his friends were confined, with the vague notion that he might be able to help them in some way. He was seen, arrested on suspicion, and found to be "wanted."

M. and N. were sent to the Bridewell to have their criminal education finished by a post graduate course under older and more hardened criminals, and served their terms. V. was sent to the John Worthy school and afterwards released by the Mayor.

Here was society's opportunity to study the young malefactors and their family histories, and to so supervise their subsequent lives as to give them an opportunity to develop into decent citizens. No further attention was paid to them, however, until they committed the crime for which they afterwards were hanged. It would have been cheaper to have prevented their crimes by making, if possible, decent citizens of them. It surely was well worth the trial.

In passing, it might be well to reflect on the bearing of such histories as the foregoing upon sterilization in social therapeutics. For many years I have been advocating operations upon the sexual organs as a preventive of crime and allied social phenomena.

In 1895, in my "Diseases of Society," I presented sterilization by resection of the vasa deferentia as a most effective remedy for "social diseases" of all kinds. Its role in the prevention of social disease seems obvious enough.

It has seemed to me peculiar that in the midst of the present furore regarding sterilization, some of my brethren have not been courteous enough to mention my pioneer work along this line, but I have consoled myself with the tardy endorsement which even plagiarism, discourtesy, or the writings of those who are ignorant of work which has gone before sometimes gives to the hobby-rider. It matters not who popularizes a principle or method so long as it is beneficent.

815 Reliance Building.

*Mrs. N. died shortly after the above was written. Cause of death unknown to me at present writing.

REPORT OF A CASE OF SARCOMA OF THE ADRENAL GLAND.

By J. J. HOFFMAN, M.D.,
ASSISTANT PHYSICIAN,
AND
J. ALLEN JACKSON, M.D.,
PATHOLOGIST, CENTRAL INDIANA HOSPITAL FOR THE INSANE,
INDIANAPOLIS, INDIANA.

The following case is of interest on account of the location, the gross appearances, the exceedingly vascular nature, and the chemical reaction of the growths. The chemical reaction referred to is that described by Hall in the *Archives of Internal Medicine*, Vol. II, No. 4, p. 357. From his article we quote the following: "A considerable amount of work has been done on these tumors and some peculiar reactions have been described as specific. Croftan claims that a watery extract of these tumors injected into dogs and rabbits produces glycosuria, that it converts uncooked starch into dextrose and maltose, and that it decolorizes boiled starch stained with iodine. The writer has subjected all tumors reported in this paper to the last two tests and found the reaction described in every case. Control tests with other neoplasms have constantly failed. Thus it seems that the chemical properties are no less interesting than the microscopical and clinical features."

The secondary nodules in the lungs in this case were submitted to the following test. Pieces were triturated in a mortar with a small quantity of water. Strips of filter paper were placed in boiled starch, the starched filter paper was then touched

with iodine. These strips of filter paper, which held the starch acted upon by the iodine, were then placed into the watery solution of the tumor and were decolorized in from five to ten minutes.

Clinical History.—N. M. B., age 52 years, was admitted to the Central Indiana Hospital for the Insane, September 10, 1908. Her condition upon admission and prior thereto is unknown. Her family history is also unobtainable. Her mental condition upon admission is recorded as being irritable and quarrelsome, with a tendency to do violence. The course of her mental condition has been one of gradually increasing dementia. She has lost weight and energy. Physical examination made upon September 16, 1908, revealed the following: Rather emaciated senile colored woman. Eyes and face dull; mouth drooping. Skin harsh and dry. Voice rather scanning. Eyes dark, pupils unequal. The left is dilated and irregular. Does not react to light or accommodation. Mouth large, teeth fair, odor offensive. Mucous membrane pale, tongue thick and flabby. Thorax contracted in all diameters. Dullness upon left side upon percussion. Marked decrease in the vesicular murmur over the left lung. There is reduplication of first and second sound. Harsh bruit best heard at apex. On account of the mental condition of the patient the abdominal examination is rather obscure. There appears to be enlargement of the liver. The liver appears nodular. The border of the liver cannot be felt readily. Generative organs negative. Reflexes very active. Gait slow and measured. Station and coordination good. Muscular strength fair.

Present Illness.—The onset of the present illness is very indefinite. She gradually lost flesh. Complains of pain and tenderness over right hypochondrium. She complains of cough and pain in chest. She has marked cachexia. Physical examination does not vary from previous examination. A provisional diagnosis of pulmonary tuberculosis with malignant tumor of the liver was made. The patient died January 15, 1909.

Pathological Report.—Body that of an emaciated senile female. Rigor and livor mortis present. Teeth not well preserved. Pupils dilated and equal. No external signs of traumatism or disease. On the anterior surface of the right tibia, in its middle portion, there is an irregular bony elevation. The ankles are edematous.

Circulatory System.—Pericardium and sac negative. Heart shows chronic interstitial myocarditis. Aorta shows moderate arterio-capillary fibrosis.

Respiratory System.—Marked chronic bilateral pleural adhesions. Left lung is voluminous, and emphysematous blebs are seen along the anterior border. Crepitation is impaired in areas which are the seat of numerous small firm growths, some of which have a tendency to undergo softening and degeneration. The firmer growths are red in color, with yellowish centers of a cheesy nature. Otherwise the lung is normal in color and shows slight congestion and edema. Right lung shows nodules considerably larger than those in the left. One at the base upon the diaphragmatic surface is larger than a hen's egg. There are other nodules in the lower lobe, which are larger than those in the upper lobe and middle lobe. These nodules are darker in color and fragmentary, and are soft in consistency. The smaller ones are more firm—while some show a yellowish area in their centers.

Alimentary System.—The muscles are pale—430 c.c. of a dark serosanguinous fluid in the peritoneal cavity. A retroperitoneal growth upon the left side in the left renal region is seen. The peritoneum is adherent to the growth in the liver. The liver is large and is the seat of numerous large growths. It measures 27 x 22 x 9 cm. The growths vary in size from a hen's egg to an orange. The largest one is upon the inferior surface at the junction of the right and left lobe. Another is seen at the inferior border of the right lobe, to the outer side of the gall bladder. Smaller ones are scattered throughout the liver—they vary from firm areas to sloughing, fragmentation, and dissolution. Otherwise the liver cuts with increased resistance and its edges are rounded, and it shows slight congestion. The pancreas is free and evidently normal. Intestines—there are chronic adhesions in the right hypochondrium at the hepatic flexure of the colon. Otherwise intestines negative. The stomach is displaced to the right and lies in the longitudinal axis of the body between the growth and the liver.

Urogenerative System.—The left kidney is small and lies to the outer side of the growth. It is bound to the mass by rather easily torn adhesions. The renal veins and the ureter are surrounded by the growth. No evidence of the growth seen in the kidney. The kidney otherwise shows chronic interstitial nephritis. The right kidney is free from growths and shows interstitial changes. The bladder shows a small stone at the trigome. Ovaries are cystic and the uterus shows two small fibroid growths at the middle of the body.

Glandular System.—The spleen is not invaded by the growth, and is apparently normal. The right adrenal is negative. The left lies at the upper anterior surface of the growth. It is regularly enlarged and no distinct nodular areas are seen. It measures 9 x 4 x 4½ cm., cuts with moderate resistance and has a grayish appearance. The main body of the retroperitoneal growth is separated from it by a firm capsule.

The thyroid and lymphatic glands show no changes.

The Tumor.—The tumor lies to the inner side of the kidney. It is retroperitoneal—large, globular in shape. Large veins are seen coursing over its surface. It surrounds the renal vessels, and is misleading as to its consistency, having a tendency to fluctuate. The cut surface shows a distinct capsule—the surface is firm, except near the center, where there is a tendency to degeneration. It is a yellowish gray in color, having a lobulated appearance upon its cut surface. The growth weighs 2660 grams.

Microscopical Report.—Sections show the tumor enclosed in a fibrous capsule 1 mm. thick. At one point only do we see a prolongation of the fibrous elements of the capsule extending into the tumor structure and here it is very scanty. The connective tissue binding the component parts of the tumor is very scanty in comparison with the cellular elements. The blood-vessels are few and those seen are in the interstitial elements with some few capillary arrangements in the cellular elements. The coats of the vessel are indistinct and they appear as sluiceways. The elements beneath the capsule present an arrangement simulating the cortical portion of the adrenal but no distinct acini or tubular arrangements are present. The cells here are small and large, round, with a few spindle cells, and these are closely compact.

The cortical portion of the left adrenal, save for slight congestion, is fairly well preserved. The arrangement of the medullary portion is distorted. The interstitial elements can not be outlined, and are very scanty in amount. The medullary portion contains some adrenal cells, large cells showing mitosis of the nuclei; others are small, with single nucleus. These are loosely placed with clear spaces intervening. Vascularity is poor; few, if any, typical vessels are seen.

The liver is infiltrated with large, small, round cells, obliterating the normal liver elements. The connective tissue is scanty, the vessels are few, cells compacted, and there is no glandular arrangement. The lung shows a similar picture as that described in the liver except the sections show more healthy lung tissue and the infiltrating cells appear as more or less circumscribed area, with some diffuse infiltration. The other organs microscopically present pictures characteristic of the conditions given in the pathological diagnosis and are here omitted for the sake of space. The general enlargement and absence of secondary nodules in the adrenal point to the adrenal as the primary seat of the malignant growth, and even though it responds to the chemical test for hypernephroma, the anatomical and microscopical findings lead us to regard it as a sarcomatous condition.

We are indebted to Dr. E. D. Martin for his assistance in the pathological examinations.

ANCHORING THE KIDNEY FOR DISLOCATION OR DISPLACEMENT.*

By EDWARD N. LIELL, M.D.,

JACKSONVILLE, FLORIDA.

A MISPLACED or dislocated kidney, though frequently a congenital condition, is usually acquired. As to the terms "floating" and "movable," applied to the kidney, these are merely relative. The former may be defined as a kidney displaced from its normal position—not fixed, a peritoneal envelopment permitting of a rather free movement; the latter is mobile in the tissues by which it is surrounded. The tendency of the kidney to gravitate from its normal position is associated with several factors, chiefly, however, with that of absorption of the peritoneal fat and consequent relaxation of its folds.

A few words here as to the normal position and surgical relations of each kidney. Regarding the former, a line drawn through the umbilicus is below the lower border of the kidney; moreover, the axis of the kidney is obliquely downward and outward. As to the surgical relations, the right kidney is in contact in its upper three-fourths, separated by peritoneum, with the posterior and under surface of the liver, and below with the colon and duodenum; while the left kidney, in its upper portion, lies against the posterior surface of the stomach, the extremity of the pancreas, and the spleen, its lower portion being in contact with the colon and coils of small intestine.

In examining for displaced or dislocated kidney, the patient should be in a semi-reclining position, thus relaxing the abdominal muscles. Bimanual palpation will detect the presence of a tumor or solid mass in the hypochondriac region, its shape conforming to that of the kidney when readily felt. This is reducible in the direction of its normal position, or by gravitation when the pelvis is elevated. Not infrequently the mobile kidney has an extremely wide range, shifting to and fro in the loose perinephritic and peritoneal folds. Undue manipulation may cause the patient to have a sickening sensation or even to faint.

The advantage the lumber incision possesses in operation upon the kidney is that, not only is the latter readily reached, but it affords good drainage in addition to the non-opening of the peritoneum. As a prerequisite to operation, the patient should be placed in a lateroprone position the reverse of the side operated upon, the iliocostal space being increased by placing a sandbag or firm pillow under the opposite loin.

The incision most practical is an oblique one to the outer side of the quadratus lumborum muscle, from the last rib downward and outward towards the crest of the ilium, the length of the incision being not over three inches. The retroperitoneal space and fatty tissue of the kidney is readily reached after division of the firm lumbar and transversalis fascia. By the aid of the retractors, and an assistant making pressure anteriorly, the perirenal fat looms up in the wound and the kidney is brought to view and thus held in position. Right here I would add a warning as to three factors to be considered: be careful not to open the peritoneum, though if immediately sutured no harm will come of it; do not twist the kidney, obviously avoiding any injurious effect upon the ureter and vessels; third, there is no occasion, at any time, for exposing the kidney wholly by attempts to deliver it through the wound.

To continue with the operation: the fibrous capsule of the kidney is next gently incised along the convex border for about two inches, and reflected back for half an inch on each side by means of the handle of the scalpel. If the incision be inadvertently carried into the kidney substance, considerable bleeding will be met with, which, however, will yield to hot water sponging. Two sutures, number two chromicized catgut, are then passed through the aponeurotic tissue of the wound on one side, continuing it through the everted flap of the capsule on the same side, at the lower pole of the kidney, then lightly through the substance of the kidney and the everted capsule and aponeurotic tissue on the opposite side. Before tying the sutures the kidney should be pushed or drawn into its proper place; each suture should take a firm hold, care being taken, however, not to draw them so firm as to fix the kidney wholly or in part in the main wound.

In closing the latter, I use number two plain catgut as buried suture for the fascia and aponeurosis; the muscle and skin being brought together with several silkworm-gut sutures. The entrance and exit of these silkworm-gut sutures are merely on the edges of the skin, thus giving an improved cosmetic effect.

This method of anchoring the kidney and overcoming the distressing symptoms of displaced kidney is easy and efficient, having given me excellent results in my last five cases operated upon. A failure to give permanent relief may be attributed to two factors: either that operation has been performed in unsuitable cases, as in a coexisting general visceral ptosis, or to imperfect technique and suturing.

*Read at the Thirty-seventh Annual Meeting, Florida Medical Association, held at Jacksonville, Fla., April 6, 7 and 8, 1910.

TWO CASES OF ACTINOMYCOSIS.

By HOWARD JONES, A.M., M.D.,

CIRCLEVILLE, OHIO.

THE issue of the MEDICAL RECORD of June 4 containing two articles on actinomycosis by Dr. Wood and Dr. Stengel suggests this report of two cases.

On May 3, 1909, a young man consulted me in regard to a swelling on his gum just above the left upper bicuspid. The history was that of ulceration of the tooth following a too-long-delayed filling. The abscess was opened by me at once, and nothing more was heard of the patient until June 30, when he again called at my office on account of a swelling in his left cheek. It showed slightly on the outside and projected considerably within the mouth. It was about the size and shape of a large chestnut, and felt very hard and firm, much more so than an abscess.

Having in mind the tooth, now entirely well, I suggested he might expect to have pus in the tumor and that it had come from the previous infection. The growth increased in size rapidly. By August 1 it was as large as one inch and one-half in its greatest diameter and was more inclined to be spherical than before. There was neither redness on the outside nor anything that suggested pus. Actinomycosis then came to my mind and a tentative diagnosis was made. In about two weeks the skin was red over the growth and looked as if it would soon break down. August 18 the skin was cut and with a pair of dressing forceps a pinch was taken from the growth and mounted for the microscope. The specimen proved to be excellent, and the diagnosis of ray fungus was confirmed. The tumor was then removed and the cavity thoroughly washed with a solution of sulphate of copper strong enough to be decidedly blue. A piece of gauze saturated with a weaker solution was then packed in the cavity and left for ten minutes. On the withdrawal of this the wound was packed with moist carbolated gauze. No other treatment than redressing with the carbolated gauze was resorted to. The wound soon healed with but a slight scar.

Another case, in a young woman, also started in a carious tooth. When first seen by me there was a tumor in the right cheek and one just above the right clavicle. The one on the cheek had ulcerated through the skin and the characteristic yellow granules could be seen with a magnifying glass in the scanty discharge. The lump above the clavicle was red and looked as if it, too, would soon break down. Again the microscope showed the ray fungus as the cause.

The patient felt ill but had no fever. Potassium iodide was given in increasing doses for one week and the tumors then removed. The sulphate of copper treatment was used as above described and the wounds healed rapidly. About this time a swelling was noticed on the sternal end of the left clavicle. Instead of forming a spherical mass as in the lesions removed, it spread over the whole clavicular region and was without defined edge. This growth has persisted now for about four months, and reaches from about one inch above the clavicle to the breast line, is sore in spots on pressure, and has a board-like feel. The clavicle throughout its length is about twice its normal width and the growth seems to be underneath as well as on the outward surface. The ribs seem to be involved also. An exploratory incision to the bone of the clavicle, at the sorest and most swollen point, failed to give any evidence of actinomycosis. Potassium iodide has been increased to 180 grains per day without apparent benefit. Operation has been declined. The patient is gradually failing in health and it looks as if surgery is her only chance of relief.

The copper salts, especially the sulphate, are very active fungicides, and it has occurred to me that they might be used with good results against the numerous species of actinomyces by some method of depositing the copper by electricity in the invaded tissue.

Acute Thyroiditis and Its Cardiovascular Complications.—Jacques Parisot states that most infectious diseases may produce lesions of the thyroid gland by inflammation. He gives histories of cases in which thyroiditis with cardiovascular symptoms accompanied puerperal streptococcemia, typhoid fever, mumps, and pneumonia. There occurred tachycardia, dissociation between the pulse and temperature, localized pain, and palpitation. The vasomotor reactions may be exaggerated; the arterial pressure is markedly lowered, and the pulse becomes depressible. These symptoms are transitory, and disappear with the disappearance of thyroid congestion. They seem to be due to a hypersecretion by the thyroid which is passing, and causes temporary symptoms of poisoning. They are similar to the symptoms that appear after operations on the thyroid.—*La Presse Médicale.*

Morbid Associations and Immunization.—V. Hutinel gives interesting examples of the coincidence of various forms of infectious diseases in children and adults, and formulates his conclusion, that two such diseases when associated modify one another and interfere with the natural process of immunization, which is necessary for the cure of disease. Typhoid is increased in its duration, its severity is aggravated, and relapses are more frequent when any other infectious disease accompanies it. Syphilitic lesions sometimes disappear at the beginning of a typhoid, to reappear in a much more severe, sometimes a fatal, form after the fever has passed. Experiments in immunization in animals show that there is an interference when two diseases are inoculated at the same time. The author questions whether this is the result of interference with phagocytosis, since bacterial products lessen the activity of the leucocytes both directly and by their effect on the nervous system.—*La Bulletin Médical.*

Meningism: Its Relations with Lumbar Puncture.—Louis Bousquet wishes to establish a means of diagnosis between true meningitis and the so-called meningism, and has experimented as to the possibility of establishing a test by means of lumbar puncture. He describes, under the head of meningism, the clinical manifestations of meningitis, without pathological conditions corresponding to them which we see in hysteria and reflex meningism. Some of these conditions are toxic, others are due to intestinal poisoning. Lumbar puncture in most cases is of great value in establishing the differential diagnosis between these conditions and true meningitis. At the same time these results are not always implicitly to be relied on since some of the signs fail to be present in certain cases. Cytological changes in the cerebrospinal fluid and microbian invasion are not always evident to tests made of this fluid. In difficult cases we should make use of the triple tests, cytological, bacteriological, and chemical, and it should be considered whether there are any leucocyte alterations.—*Gazette des Hôpitaux.*

The Influence of the Cerebellum on the Coordination of Words.—G. Garbini considers it demonstrated that the cerebellum exercises a coordinating action on articulate language. The demonstrative cases are those of Sanloeffer and U. Rosso, the last of which was confirmed by autopsy at the *Instituto Umbro,* in May, 1906. The macroscopic and microscopic characteristics were shown of atrophy and total sclerosis of the cerebellum. The authors record that the subject in life had presented a pseudobasilar syndrome, and articulated language was changed by disturbances of speech, dysarthria, dysphasia, and bradyphasia. He thinks that the regulatory mechanism is in the cerebellum, and impulses pass out by the system of cerebello-rubro-thalamic neurons, and run through the *ansa nuclei lenticularis,* and the *putamen,* to produce their regulative action. This has a marked importance in its effect on the mechanism of words, the impulse for which passes through this nucleus by a certain number of fibers deputed to articulate language.—*La Riforma Medica.*

CELLULAR TENACITY AND PATHOLOGY.

THE problems of disease are ultimately resolved into problems of cytology. The specific energies of the cells confront one at every step in the investigation of pathological phenomena, whether of metabolic or zymotic origin. The conception of specific energy as first applied by Johannes Müller in 1826 to the nerves has later expanded to include every form of vital unit, and coupled with Virchow's doctrine of cellular pathology, it forms the foundation of modern pathological physiology.

There is one phase of this subject that has not been sufficiently emphasized, namely, the inherent tendency of all cells to persist in a given form or direction of activity. The expression, "cellular tenacity," is applied to this phenomenon by W. von Leube, in a valuable contribution in the *Zeitschrift für klinische Medizin*, Vol. 70, Nos. 5 and 6. This observer notes that as the result of certain injurious influences a quantitative change in the normal cellular activity is usually the sole expression of the disease process. Qualitative changes in cellular activity are extremely rare, and are to be attributed to persistent and unusual stimuli causing intracellular atomic rearrangements. These are accompanied by qualitative transformations of the normal activity of the cells. Of eminent importance is the fact that when once these changes are established they have a tendency to persist by virtue of the inherent tenacity of the cells.

Illustrations of these facts are amply furnished by both clinical and experimental phenomena. The formation of antibodies in natural or artificial active immunization represents a specific reaction of the cells. This immunity may exist for a longer or a shorter time; in either case the disappearance of the antibodies is not necessarily associated with the loss of those intracellular atomic readjustments that were instrumental in yielding these antibodies. A new infection, as in typhoid, excites a prompt and vigorous elaboration of these protective substances. Thus it had been shown by Cole that a minimal inoculation with a typhoid culture will not evoke the production of agglutinins in a normal rabbit, but will do so in a rabbit that had already produced agglutinins upon inoculation, and from whose blood these substances had disappeared. Furthermore, this reawakening of a former intracellular rearrangement may be evoked by other than specific stimuli. Thus, small doses of pilocarpine increase by one-third the amount of antitoxin in the blood of a horse actively immunized against diphtheria. Prof. von Leube has investigated this phase of the subject in patients that had recovered from typhoid fever. He found that the production of Bier's passive hyperemia in the extremities, or the administration of an abundant diet, was instrumental in stimulating the elaboration of agglutinins when the tendency to produce these had already become latent. It is a fact established by both clinical and experimental evidence that the stronger the original infection the greater does this latent tendency become. It has been shown by numerous observers that when the temperature is artificially raised in animals that have been inoculated they are enabled to resist the infection more powerfully. Lüdke has found that the prolonged application of external heat may arouse the latent tendency to produce agglutinins in animals that had been inoculated with typhoid bacilli. The injection of deuteroalbumose had the same effect.

The diseases of metabolism, namely, obesity, gout, and diabetes, furnish striking illustration of the tenacity with which intracellular atomic rearrangements persist, after these have once been produced by abnormal external conditions. The pathological tendency to excessive fat formation, whether inherited, or acquired as the result of overabundant diet, indulgence in alcohol, deficient exercise, or residence in a warm climate, represents a disturbance in the normal activity of the cells, which disturbance is apt to persist for a long time, or even permanently, after the original causes have been removed. Similarly in gout, the disturbance in the endogenous metabolism of uric acid continues long after the removal of the inciting factors, chiefly dietetic and other hygienic errors; and even when the gouty manifestations have been removed the disposition remains latent, to be aroused by a return to former errors of living. The same tendency is observed in diabetes. This cellular inertia accounts for the obstinacy of these metabolic disorders, and necessitates that the treatment be continued for a long time, and the cells restored to their normal mode of functioning by easy stages.

DEATHS UNDER ANESTHETICS.

THE question of the best and safest anesthetic for general and special use, and of the administration of the same, has been widely debated in all civilized countries of late years. Of course, the chief arguments have been between the supporters of chloroform and ether, and although no definite agreement has been come to, it is somewhat significant to note that of the eighty inquests or so held by the coroner of the City of London during the past nine years nearly all have been on patients who have died in hospital while under the influence of chloroform or of mixtures containing chloroform administered for the purpose of operating. But it would be idle to enter here into the comparative merits of chloroform and ether as anesthetics, except to draw attention to the apparently large num-

ber of fatalities which follow the administration of chloroform in Great Britain.

The matter which is engaging the attention of the medical profession to a great extent is with regard to the administration of anesthetics. In England the contention is made that anesthetics are too frequently administered by unskilled persons or by individuals not sufficiently conversant with the safest methods of giving them. It is argued that whenever possible the anesthetic should be given by a thoroughly competent anesthetist. A pertinent object lesson on the danger attending the administration of anesthetics, in this case ether, has been afforded recently in London. A patient died in Guy's Hospital on July 2 under the influence of ether which had been given him by the house surgeon by the "open" method. Dr. Waldo, the coroner for the City of London, at the inquest held on the above case remarked that, with regard to Guy's Hospital, he had noticed that in nearly every one of the forty-four cases in which death occurred under anesthetics during the past nine years the anesthetic had been given by junior residents. In another large general hospital during the same period, at which it was the custom for the anesthetic in serious cases to be given by visiting and resident specialists, there had been fewer fatalities. The acting resident surgeon at Guy's Hospital said that in consequence of strictures passed by Dr. Waldo, at a former inquest, on the body of a woman who had died under chloroform given by a junior resident, certain reforms had been introduced, including the requirement that all candidates should, before appointment on the junior staff, produce evidence of special knowledge in the administration of anesthetics. Since the introduction of reforms in this respect at Guy's Hospital fatalities have greatly decreased. In 1907 there were eleven deaths from this cause in the institution, while since that year, and after reforms had been brought in, the deaths reported have been few and far between.

However, there is no necessity to labor the point that reforms are called for in the mode of administration of anesthetics in England, for experts there are practically unanimous in asserting that more skilful administration is demanded. Indeed, so strong is this belief that at the meeting of the British Medical Association, just held in London, in the section of anesthetics the resolution was passed that the British Medical Association recognize the need for the proposed legislation as to the administration of anesthetics in the interests of public safety.

In the MEDICAL RECORD of July 9 was a letter on the subject by Mr. Frederick S. Crum, in which he discussed the British Parliamentary report recently published, and suggested that most, if not all, of the conclusions and recommendations contained in the report were equally applicable to this country. Whether the administration of anesthetics is conducted more safely in America than in Great Britain is a matter of little moment. The salient feature of the situation in both countries is that in no case should an anesthetic be administered unskilfully, and that wherever possible the greatest available skill should be employed. This is to say, that every medical student should have some training in the administration of anesthetics, and that in every large hospital there should be a resident anesthetist who should instruct the internes in the art of administering anesthetics as well as giving them himself in serious cases.

THE ACTION OF LEUCOCYTE EXTRACTS.

THE researches published in 1908 by Hiss and Zinsser as to the curative action of substances extracted from leucocytes in various diseases, but more especially in pneumonia, attracted more than passing notice. The therapeutic value of such extractives was established at that time, and has been confirmed by later observers. Their *modus operandi,* however, has never been made clear, and the leucocyte, which has received at one time or another the credit for most of the beneficial and also the injurious activities of the animal body, still remains in many respects something of a mystery. In the June number of the *Journal of Medical Research* Zinsser reports some later researches carried on in the hope of determining the intimate action of the leucocytic extracts. As a result of these investigations the author is enabled to make some fairly definite positive and negative statements as to the leucocytes and their extracts.

He has found that extracts from normal rabbit leucocytes have distinct bactericidal powers for pyogenic staphylococci and typhoid bacilli. The action of various lots of such extracts upon the same strain of microorganisms is fairly uniform, and separate strains of the same species of organisms show no decided variations in their susceptibility to the bactericidal substances in the extracts. The more marked thermostability of the bactericidal substances in the extractives, they requiring a temperature of 75° C. to destroy them, justifies the conclusion that they are not identical with the bactericidal substances in the serum. Addition of fresh leucocyte extract does not reactivate the substances which have been rendered inert by heating to 80° C. While definitely present, the bactericidal substances of the leucocytes are quantitatively insignificant as compared to the bactericidal powers of normal serum, and it is very unlikely that they have taken any but a secondary activity in combating infection in the living body. The theory that the leucocytes were the source of complement could not be confirmed, as no trace of complement could be found in the extracts of washed leucocytes. Finally, immunization had no apparent effect upon the bactericidal power of the leucocytic substances.

From these findings it would appear, as Zinsser himself suggests, that the bacterial substances contained in the leucocytes, and extracted therefrom, have no activity as applied to the body at large, and no relation to the production of immunity. Their action would rather appear to be merely the destruction of the bacteria which have already become ingested by the corpuscle during its activities as a phagocyte.

The Condition of the Heart in Pulmonary Tuberculosis.

Dr. John Hay, writing in the *Medical Press and Circular*, July 13, points out that pulmonary tuberculosis is relatively infrequent in those affected by valvular disease of the heart, and that the converse of this is also true. Tuberculous disease seems in some peculiar way to inhibit the development of the valvular trouble. In 1898-1907, among 109 autopsies made in the Royal Infirmary, Liverpool, on patients suffering from all types of pulmonary tuberculosis, only 4 per cent. showed evidence of valvular disease of the heart. Brown states that in 8,154 autopsies made upon phthisical patients, 293 were found to be suffering from cardiac disease, which gives 3.5 per cent. Meisenberg found that among all the patients at the Leipsic Clinic from 1889 to 1898, 1.75 per cent. had heart disease, while the percentage suffering from heart disease among those affected with pulmonary tuberculosis attending the clinic during those years was only 1.14 per cent. However, endocarditis may occur as a complication of pulmonary tuberculosis, but in most instances it is either a terminal affection or is due to streptococci or staphylococci and is verrucose in type. Specific tuberculous endocarditis is of all forms the least common. Tuberculous pericarditis must also be classed as another not infrequent terminal event in pulmonary tuberculosis. It very rarely develops in the absence of tuberculous disease. Elsewhere Hay draws attention to the fact that when pulmonary tuberculosis and valvular disease do coincide, the treatment of the two affections is not antagonistic. Rest, which is such an important feature in the management of tuberculous patients, is also an essential to an overworked heart. In the later stages the usual cardiac tonics should be employed. In the earlier stages there should be complete rest, careful dieting, freedom from emotional excitement, and specific vaccine therapy when available.

The Initial Work of the Crocker Cancer Research Fund.

Notwithstanding the large amount of work done in the last decade in the experimental study of cancer, and the elucidation of many biological questions relating to the pathogenesis of the disease, we are still in the dark about its etiology and specific therapeutics. Early diagnosis and early operative treatment are as yet our main reliance in the struggle against the disease. It is therefore satisfactory to learn from the paper of Dr. Levin, published elsewhere in this issue, that the George Crocker Cancer Research Fund of Columbia University has undertaken to make examination of suspected tissue, provided the physician furnish the information needed for its statistical investigation of the etiology of cancer. For some time to come the propaganda of early diagnosis and the clinical analysis of a large number of cancer cases will be of as great importance to the patients and the profession as the experimental study of the disease. The profession should avail itself of this new opportunity. The Department of Health of the City of New York has agreed to cooperate with the Department of Pathology of Columbia University and by the middle of October each collection station of the board will be supplied by Columbia University with jars to be used for specimens of cancer tissue.

News of the Week.

Civil Service Examinations.—The United States Civil Service Commission announces an examination to be held on October 5, 1910, to secure eligibles to fill a vacancy in the position of medical interne in the Government Hospital for the Insane, Washington, D. C. The salary is $600 a year and maintenance, with opportunities for advancement. Qualified persons are urged to enter the examination, as difficulty has been experienced in filling these positions in past years because of the limited number of eligibles available. Application for further information should be made to the U. S. Civil Service Commission, Washington, D. C.

The New York State Civil Service Commission will hold examinations on September 24, 1910, to fill a vacancy in the position of clinical pathologist in the Cancer Laboratory at Buffalo. This position carries a salary of $2,500 a year, and is open to men only. Examinations will be held on the same date to fill the positions of physician at the Lakeview Sanatorium, Troy, at a salary of $1,000, and of trained nurses in State institutions at salaries of from $420 to $600. For detailed information application should be made to the State Civil Service Commission, Albany, N. Y.

Health of the Canal Zone.—During the month of June, 1910, the annual death rate for all employees and from all causes was 10.66, which is slightly higher than the rate for the same month of last year, 9.34. The increase occurred only among the black employees, for whom the rate was 12.80 in June, 1910, and 9.32 for June, 1909. For white employees the rate fell from 9.44 in June, 1909, to 4.50 in June, 1910. The total number of employees was 51,767, and the total number of deaths, 46. As was feared after the heavy rains in May, the month of June showed an increase in the number of cases of malaria, these amounting to 1,253, with 8 deaths. The annual death rate for the Canal Zone and the cities of Panama and Colon was 20.38 in June, 1910, as compared with 16.42 for June, 1909. No cases of plague, smallpox, or yellow fever occurred on the isthmus during the month. Quarantine against Costa Rica has been in force because of the yellow fever in the latter country. From the Government hospitals the surgeons report 154 operations, with 3 deaths. In Panama an inspection has been made in order to determine the character and conditions of buildings from the standpoint of offering places for harboring rats. This is of great importance because of the intimate connections between Panama and plague-infected ports. Of 1,349 homes inspected, 239 were found in bad condition, many of them providing ideal places for the breeding of rats. A partial examination of the gutters in the city also has shown that at least 85 per cent. are in bad condition.

Cholera in Europe.—A number of cases of cholera have been reported in the province of Bari, Italy, occurring principally in ports along the coast of the Adriatic. Active measures have been taken by the Italian Government, and the indications are that the disease will soon be under control. In Germany, also, preventive measures are in force to guard against the importation of the disease from Russia. The total number of cases for the present year up to August 13 in Russia is given as 112,985, with 50,287 deaths, a mortality percentage of 44.5.

These are the official figures furnished by the Government Sanitary Bureau. During the week ending August 20, 6,741 cases of the disease were reported with 3,021 deaths. In St. Petersburg, owing to better hospital facilities, the mortality percentage is somewhat less than in the provinces; and as the number of cases has considerably decreased, it is hoped that the epidemic is on the decline.

Bar Public Drinking Cups.—As the result of an order issued by the Wisconsin State Board of Health, railway trains will not carry public drinking cups in that State after September 1. Trainmen on roads crossing the State have received orders to put the cups in hiding when the Wisconsin State line is crossed, and not to restore them to their usual place until out of the State.

New Tuberculosis Camp.—The Middlesex County Tuberculosis Camp, at Cromwell, Conn., was opened recently. The camp consists of a central administration building, with a number of tents and shacks for the patients.

Nurses' Home.—The Robert Kinlock Home for Nurses, on the grounds of the Roper Hospital, Charleston, S. C., was formally opened on August 4. Accommodations for forty nurses are provided.

More Centenarians.—John Kipp, 103 years old, died in the Warren County, N. J., Almshouse, on August 19. He was of small stature and at the time of his death weighed only sixty pounds. In Reading, Pa., Mrs. Chloe Walker, colored, the oldest resident of the city, died on August 17. According to her relatives she was born in slavery in Virginia, in 1802, and was therefore 108 years old. Margaret Johnson, reputed to be the oldest person on Long Island, died at her home in Bayside recently. On the death certificate the date of birth was given as May 15, 1800, making her over 110 years old.

Plague in Ecuador.—Ten cases of bubonic plague were reported in Guayaquil during the first two weeks of August.

Aid for Japan.—The American Red Cross Society, through the State Department, has telegraphed $5,000 to Japan, for the relief of the sufferers from the flood in that country. The money will be distributed by the American Embassy.

Dr. Anita Newcomb McGee has been appointed chairman of the Health Department of the California Federation of Women's Clubs. Dr. McGee is well known for her work during the Spanish-American and Russo-Japanese wars.

Dr. Charles Stover of Amsterdam, N. Y., becomes president of the Medical Society of the State of New York through the death of Dr. Charles Jewett recently. Dr. Stover, who was elected to the vice-presidency last January, is a graduate of the University of Pennsylvania Medical Department, and attending physician to St. Mary's and the Amsterdam City Hospitals.

The Shenandoah Valley Medical Association, composed of physicians in Virginia, was organized at a meeting held in the Winchester Hospital recently. Dr. D. D. Carter of Woodstock was elected president, and Dr. Walter Cox of Winchester, secretary-treasurer.

American Association of Clinical Research.—The second annual meeting of this Association will be held in Boston under the presidency of Dr. E. S. Bailey of Chicago on September 28 and 29, 1910. Contributions on Researches in Medicine and Surgery, in Prophylactic and Anaphylactic Medicine, in Mental Medicine, in Radiotherapeutics, in Metabolism, etc., are promised. There will also be a public meeting. The secretary of the association is Dr. James Krauss, 419 Boylston street, Boston, Mass.

Obituary Notes.—Dr. L. Drakeley Rood of Des Moines, Iowa, a graduate of the Medical Department of the University of Vermont in 1881; a member of the Iowa, Vermont, Connecticut, and Massachusetts State medical societies, the American Medical Association, the Hampshire and Polk County Medical Societies, and the Tri-State Medical Society, and a member of the Board of United States Pension Examiners, died at his home from septicemia, on August 8, aged 49 years.

Dr. J. Adam Krug of Philadelphia, Pa., a graduate of the Medico-Chirurgical College of Philadelphia in 1889, and a member of the Philadelphia County and Pennsylvania State Medical Societies, died at his home on August 6, aged 54 years.

Dr. Benjamin H. Detweiler of Williamsport, Pa., a graduate of the Medical Department of the University of Pennsylvania in 1855, a member of the American Medical Association, and of the Philadelphia State and Lycoming County Medical Societies, the senior practising physician of Lycoming County, and a trustee of the State Hospital for the Insane, at Danville, died at his home on August 9, aged 79 years.

Dr. William H. Hell of Essex, Mass., a graduate of the Harvard University Medical School in 1865, a veteran of the Civil War, and for thirty years a practitioner in East Boston, died at his home on August 9.

Dr. Samuel B. Bailey of Higganum, Conn., a graduate of the Eclectic Medical College of Pennsylvania in 1859, died at his home on August 11, aged 84 years.

Dr. Lycurgus Coon of Springfield, Mo., a graduate of the Physio-Medical Institute of Cincinnati, Ohio, in 1866, and a veteran of the Civil War, died at his home, on August 6, aged 75 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ROYAL VISIT TO THE LONDON HOSPITAL—BRITISH MEDICAL ASSOCIATION—TRELOAR CRIPPLES' HOME AND COLLEGE—LECTURES—DENTAL CONFERENCE—FEVER IN DURHAM COUNTY—ANTHRAX—OBITUARY.

London, August 5, 1910.

The Royal visit to the London Hospital, which I mentioned last week, was a great success. Throughout the long journey the streets were crowded both on the route going and on that returning. The drive, extending altogether over nine miles of streets, was not in state, and soldiers did not line the route. Their Majesties were only attended by an escort. The ancient ceremony at the entrance of the city was but a symbol of the past, occupying two or three minutes. The King and Queen exhibited great interest in the Finsen Light treatment, the lamps for which were presented by Queen Alexandra. Dr. Segueira, who has charge of the department, explained the present position of this remedy. Several of the wards were visited and the patients were gratified by the kindly words spoken to them by their majesties.

Yesterday Lord Rothschild announced that as Treasurer of King Edward's Hospital Fund, he had received a check for £500, with the intimation of the King's gracious intention to augment His Majesty's annual subscription of that amount to one thousand per annum to the fund. The check was dated July 30, as the King is anxious that the date of the augmentation should coincide with that of His Majesty's first visit

to a London hospital since the accession. It is obvious that King George will continue that interest in hospitals which was so constantly manifested by his revered parents. There were various incidents besides those I have mentioned which showed the interest of the King and Queen in the work of the London Hospital, which has for years been an object of their care.

The meeting of the British Medical Association closed on Saturday with a series of excursions. There is not much out of the common in a trip to health resorts, and many members were in a hurry to go home after their week in town. About 120, however, went to Brighton and were entertained to luncheon by the local branch and at a garden party by the Mayor. Some 200 visited Bath, which still claims the premier place among our spas, and were provided with luncheon at the Guildhall on the invitation of the Mayor and corporation. I think the most interesting trip was that to the Cripples' Home, established by Sir Wm. Treloar. Some 300 accepted Sir William's invitation, Luncheon was served in the recreation room. Besides this and the usual features of such a reception, a brief review of the circumstances under which he established the Home and College was given by Sir Wm. Treloar, and some other speeches were made. But what was a little out of the way in such excursions, and perhaps the more interesting, was a mixture of science with pleasure. A paper was read by Dr. Morgan on the treatment of tuberculosis in bone, for which he said the three essentials were rest, good food and fresh air. He described an apparatus for spinal and hip cases designed by the resident medical officer, Dr. G. Gauvain, which permitted free movement and enabled the patients to be taken out of doors and into the schoolroom. Dr. Gauvain himself described the method of treatment, which he believed had proved very beneficial, and he gave a demonstration in the plastic room on the uses of plaster of Paris. The college boys were inspected by the visitors at their physical drill.

With regard to the sections much difference of opinion is but natural. The great increase in their number seems to aim at including as much as possible in the general proceedings, and the attractions of a large gathering, while at the same time encouraging the advance of specialism. Some consider that sociology should not have a section in a medical society, and some of the subjects brought forward, though interesting to everyone, are more within the purview of the statesman than the doctor. Similar objections are offered to other sections, but it may be said that only those need go who are interested, and it must be admitted that there was fair attendance at some of the doubtful discussions. On the other hand, there remains the complaint that one can only be in one place at a time, and if much interested in one subject attendance throughout its section excludes everything else.

Leaving the leading sections to your special representatives, who reported them, I will confine my notes to some other points. To-day I may refer to the odontological section, because it illustrates the objections of some to its inclusion and further because yesterday there was opened at Liverpool the Thirtieth Annual Conference of the British Dental Association, which will be continued to-day and to-morrow. The report showed that the Dentists' Act, though it is more stringent than the Medical Act, does not prevent unqualified practice, and a bill has been prepared dealing prohibition to all unregistered persons. The president, Mr. Waite, devoted his address first to the phenomenal advance in almost every detail of dental surgery, and second to the increasing prevalence of dental disease. He approved of dental school clinics for the benefit of the necessitous poor.

Returning to the section, Dr. Sim Wallace said caries was due to the lodgment of fermentable food in contact with the teeth; and discussed the proper feeding of children. It was not merely the hygiene of the mouth that made them suspect the "pap system," but that of the alimentary canal all the way along. Dr. Harry Campbell said English people's teeth were a disgrace. He attributed this largely to insufficient mastication, in consequence of which the teeth protruded too much from the gums, and we were known on the Continent as "large toothed" or "long in the tooth."

Dr. Bennett said freedom from caries was the result of simplicity of diet. It mattered little what food was taken as long as there was not much variety. Mr. K. W. Goadey dealt with the part played by the bacteria normally present in the mouth. Mr. Badcock said the mouths of animals living under natural conditions were clean, and this was due to the friction of hard food in mastication. Dr. Austin pointed out that the popular notion of injury by drugs rested on the slightest foundation. Modern research tended to show that acids developed *in situ* where the natural cleansing by the constant flow of saliva was difficult, were more likely to be injurious than medicines which did not remain in the mouth. Mr. J. G. Turner asked if teeth were necessary. One companion of his profession bewailed that civilized food gave no use for teeth; the other cried out for more teeth. In hospital practice he extracted from children of any age every septic or painful tooth. They always were the better, and he did the same for adults. The toothless could fare as well as those equally equipped. An aged friend of his, absolutely toothless, could eat the crackling of pork with relish. Patients dying slowly of oral sepsis would scarcely be recognized a few months after removal of all teeth. It was a question between beauty or sepsis.

Mr. Mummery, president of the Section, dealt with the subject of susceptibility and immunity, and expressed the opinion that there are more causes of caries than had been considered by the various speakers.

For years the County of Durham has had the highest death rate from typhoid. Attention has often been drawn to this and the blackest spots pointed out. The local government board's inspectors have emphasized the facts reported by the M. O. H., as well as district officers. Now Dr. Newsholme, the board's medical officer, has added to a report by Dr. Wheaton some scathing observations. He says the sanitary authorities of the county cannot excuse themselves by lack of knowledge and faithful counsel from their medical officers, knowledge they have had but have not passed it into duty. Ignorance of the facts now once more set out plainly cannot be regarded as much less culpable than is the failure of other authorities to utilize their knowledge. Durham is a great mining district, one person in every twenty-two of the population—men, women and children—being miners; but the evidence does not favor the conclusion that the infection is acquired in the mines, for it rather depends on the recognized causes of enteric, associated with the filthy domestic arrangements and unwholesome conditions of life rife in the county.

The President of the Royal College of Surgeons in Ireland has addressed an appeal to the Government for more equitable treatment for its medical school. Every other medical school in Ireland receives financial aid but this, the most important, is left out in the cold, although the college was originally founded with the help of a grant from Parliament. The school has done much to improve medical education and ought to be as well treated as its junior institutions.

The M. O. H. for the city reports that a case of anthrax has been notified; the patient being a housekeeper in a block of offices, one of which was occupied by a firm of leather merchants dealing in box calf and dressed leather. Of course the M. O. H. is having every precaution taken against the spread of the disease.

It is sad to record the death of a distinguished man at the early age of 44. Dr. John Edward Platt, surgeon to the Manchester Royal Infirmary and chairman of the board, died thus early yesterday. He was an Owen's College man. At the London University he took the highest degrees in medicine as well as surgery, with first-class honors, gold medals, exhibitions and scholarships. He also took the two London Colleges and proceeded to the F. R. C. S. After serving in the resident appointments, he was elected on the surgical staff of the Infirmary and became surgical lecturer at the University. He was also consulting surgeon to the consumption and some other hospitals and one of the editors of the *Manchester Medical Chronicle*, to which he contributed important articles on surgical questions, as he also did to the Encycl. Med., *The Lancet*, and the Societies.

The death on July 28 of Major William Parsons Tritton, M.D., of the Natal Medical Corps, is reported. During the Russo-Turkish war he was chief surgeon at the Lanheim Hospital, Constantinople. He was a member of the Natal Medical Society and a recognized authority on military surgery, especially on gunshot wounds.

Lt.-Col. Henry Harrison, who died on the 28th July, retired from the R. A. M. C. in 1880 on attaining the rank of Hon. Brigade Surgeon.

OUR CANADIAN LETTER.

(From Our Special Correspondent.)

TYPHOID FEVER IN MONTREAL AND IN TORONTO—THE SANATORIUM FOR TUBERCULOSIS AT MUSKOKA—THE CONSERVATION OF PUBLIC HEALTH IN CANADA—THE MEDICAL SCHOOLS OF CANADA—OZONIZATION OF THE WATER SUPPLY OF LINDSAY—SPEEDING OF PHYSICIANS' MOTOR CARS IN TORONTO—DR. CHAS. SHEARD REAPPOINTED MEDICAL OFFICER OF HEALTH OF TORONTO—AMENDMENTS TO THE CANADA MEDICAL ACT—TENTH ANNUAL MEETING OF THE CANADIAN ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS HELD IN MONTREAL—APPOINTMENT OF DR. GRÜNER AS PATHOLOGIST TO VICTORIA HOSPITAL, MONTREAL—RABIES IN WESTERN ONTARIO.

TORONTO, August 8, 1910.

TYPHOID fever is once again somewhat prevalent in Montreal and in Toronto. In Montreal the number of cases is large for the time of the year, considerably above the average; and the fear is expressed that a widespread epidemic may be apprehended. The origin of the present cases has not been directly traced to the water supply; indeed, it has been urged that infected milk and infected wells outside the city are responsible, but in an editorial which appeared in the *Montreal Medical Journal* for August the water supply is pointed to as the probable cause, and the city authorities are strongly recommended to hasten the making of the proposed filtration plant and to take other steps which are obviously necessary to ensure a pure water supply. In Toronto there have been several cases of typhoid fever which the medical officer of health frankly confessed are in all likelihood owing to polluted water. A filtration plant is being constructed for the purification of Toronto water, but slow progress is being made in its building.

The sanatoriums for the treatment of tuberculosis at Muskoka have had a reputation beyond Canada for some time. Your correspondent has been given recently the opportunity to inspect these institutions at his leisure. Mr. W. G. Gage, of Toronto, chairman of the executive committee of the Muskoka Cottage Sanatorium, invited your representative to stay at the institution so as to be able to observe its working under the most favorable auspices. Muskoka is a wild and picturesque district, dotted with lakes, situated about one hundred and ten miles from Toronto. The country resembles in many respects the Adirondack country of New York State. The Muskoka Cottage Sanatorium, with its adjacent cottages and shacks, is not unlike the Saranac tuberculosis colony. It is, however, on a considerably smaller scale. The main, or administration building, is a large wooden building, surmounted by a lofty tower, and contains accommodation for some twenty patients and the sleeping apartments of the management and the help of the institution. In it, too, are the offices, reception room, music room, dining room, dispensary, laboratory and offices of the medical staff. There are sun chambers, and along the front of the building is a broad verandah. The building, which with the cottages is placed in a well-wooded natural park of seventy-five acres, sheltered from the north and northwest. All the buildings have a southern and southwestern aspect, overlooking Muskoka Bay, the southern arm of Lake Muskoka. It is within convenient distance of the railway, and visitors and patients are conveyed to it by water and by road. The Muskoka Lake region is situated at an elevation of about 800 feet above sea level; the district is rocky and the soil porous; the air is clear and bracing, and the humidity is comparatively low. In fact, so far as climate is concerned, the country is particularly well suited to those suffering from chest affections. The main building and the cottages were presented by various donors, and are one and all adapted to the purposes for which they were built and the style of architecture is in keeping with the scenery. One of the most conspicuous internal features of the main building, and certainly one of the most instructive and interesting, is the experimental laboratory, under the direction of Dr. Caulfield, assisted by Dr. Beattie. Your correspondent was present at several of the meals, and slept in one of the cottages, so that he can personally vouch for the excellence of the food and for the good quality of the sleeping accommodation. The main building and cottages will hold from ninety to one hundred patients, and there are usually more under treatment in the winter than in the summer. The nursing staff is large and well trained, and the cottages ensure to the patients a large degree of privacy. If desired, each patient has a separate room. The open-air treatment is followed out to the fullest extent possible. Shacks have been erected, the latest of which was specially designed by Dr. Kendall, physician-in-chief. These are long, low buildings, with windows occupying the space from the roofs to half way down the buildings, and which can be open or closed as the physician may think fit. The entrance is in the middle of each building, which opens into a washing, dressing and sitting apartment for all the inmates. As at Saranac, the guiding principle of the institution at Muskoka is that it is a colony, the buildings being constructed on the cottage plan, with a main administrative building. The Muskoka Cottage Sanatorium was established in 1896.

There is also at Muskoka a large free hospital for consumptives. This is situated at about a mile's distance from the Cottage Sanatorium, nearer the town of Gravenhurst. It consists of a large main building, a pavilion and numerous shacks, and will accommodate in the neighborhood of 120 patients. There are no private rooms; all the patients are in wards. The main building is arranged and fitted in the most suitable manner possible, and the patients are housed and fed in a most comfortable and generous way. At the free hospital those who can afford to pay something do so, and at the Cottage Sanatorium each patient pays a moderate sum weekly. Dr. Kendall, the physician-in-chief, showed your correspondent over both establishments, and the result of the visit was a conviction that the situation and the treatment at the Muskoka Sanatorium left little to be desired from the tuberculosis patients' point of view. It should be said that the sanatorium at Muskoka and also the sanatorium for the treatment of tuberculosis in the vicinity of Toronto were founded and erected chiefly through the efforts of the Canadian National Sanatorium Association, established in 1896. The association, nevertheless, is a purely philanthropic organization.

The Commission of Conservation of Canada has published recently its first annual report. The question of public health is to be dealt with by the commission, including protection to infant life, improvement of the health of school children, prevention of typhoid fever and other diseases due to organic filth, and prevention of tuberculosis. Dr. Chas. A. Hodgetts, who for many years ably fulfilled the duties of secretary to the Ontario Board of Health, has accepted the position of medical adviser to the Commission of Conservation, and has left Toronto for Ottawa. In the scathing survey of medical education in the United States and Canada, by Flexner and Pritchett, some of the Canadian medical schools were severely handled. There are eight medical schools for a population of approximately 7,000,000; number of physicians, 6736; ratio, one to 1030 inhabitants. In the matter of medical schools, says the report, Canada reproduced the United States on a greatly reduced scale. Western University (London) is as bad as anything to be found in the States; Laval and Halifax Medical Colleges are feeble; Winnipeg and Kingston represent a distinct effort toward higher ideals; McGill and Toronto are excellent. The eight schools of the Dominion thus belong to three different types, the best adding a fifth year to their advantages of superior equipment and instruction. The outstanding feature of the report with respect to Canadian medical schools is the praise lavished on Toronto University Medical School, praise which, it may be noted, is well deserved. The strides made by the school within recent years have been almost astonishing, and only go to show the results which may be achieved by the expenditure of money guided by intelligence. Toronto Medical School has sprung from the ruck of such teaching institutions into quite the front rank. Of McGill Medical School little can be said in further praise. McGill has long ago won its spurs.

The ozonization by electricity of water supplies was widely advertised in Ontario a few months ago, and heralded by some enthusiasts as the coming mode of purifying water supplies on a large scale. Some experts here were skeptical in regard to the wonderful results said to have been brought about by the method of Lindsay, Ontario, and in other places. The Ontario Provincial Board of Health took up the matter and sent a bacteriologist and a chemist to investigate and report on the conditions existing at Lindsay, in connection with the ozonization plant installed there. The report shows that the glowing accounts of the success of purification by electricity at Lindsay were at least premature, and would seem to bear out the views already freely expressed by experts that ozonization of water on a large scale has not as yet proved successful. It is effective on a small scale, under certain conditions, but it is too expensive and too uncertain to be relied on when a large body of water has to be treated.

Much dissatisfaction has been expressed on the part of physicians in Toronto owing to the action of the police in summoning members of the profession who have exceeded the speed limit of motor cars when proceeding to visit patients badly injured, or dangerously ill. The magis-

trates have recognized that the position taken by medical practitioners is sound, and have allowed them some leeway when visiting such patients.

Dr. Chas. Sheard, who has held the post of medical officer of health of Toronto during the past eighteen years, and who resigned the post a few months ago, has been persuaded to reconsider his determination and has been reappointed at an increased salary.

Amendments to the Canada Medical Act were adopted at the recent meeting of the Canadian Medical Association. The bill, as it now stands, gives two representatives to each of the Provinces, to be elected under regulations to be made by the Provincial Medical Councils. All told, the Dominion Medical Council will now have a membership of thirty-one. The Laurie amendment to the British Medical Act provides that any Province may, through its Legislature, arrange a scheme of reciprocity with the British Medical Council.

The tenth annual meeting of the Canadian Association for the Prevention of Tuberculosis was held in the Royal Edward Institute, Montreal, on June 7, 8 and 9. Dr. Oskar C. Grüner, late clinical pathologist to Leeds Infirmary, England, has been appointed pathologist to the Royal Victoria Hospital, Montreal, and lecturer on pathology at McGill Medical School.

Rabies is practically extinct in Western Ontario, only three counties being now affected. Since the first case of the disease reported, in May, 1907, there have been no fewer than 481 cases notified. The result is a convincing practical illustration of the efficacy of quarantining and muzzling dogs. It is stated at the Veterinary General's Department, in Ottawa, that in Toronto alone there are now nearly three thousand fewer dogs than there were six months ago.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

BERIBERI—WAR AGAINST MALARIA—CHOLERA—PERSONAL.

MANILA, P. I., June 28, 1910.

It may be of interest to note that the recent theories with regard to the etiology of beriberi have received official recognition by the Philippine Government as well as by the United States Army. The Insular Government of the Philippine Islands has issued the following circular with regard to the use of rice, which is self-explanatory:

"In view of the fact that the Director of Health has reported to the undersigned that for some years past considerable experimental evidence that beriberi was caused by the consumption of certain kinds of rice has become available, and that at the recent meeting of the Far Eastern Association of Tropical Medicine held at Manila, Doctors Fraser of Singapore, Aron of the Philippine Medical School, and Highet of Siam, produced additional evidence that showed almost conclusively that beriberi can be caused by the continuous consumption of polished rice, and in view of the further fact that much beriberi has been encountered in the past in Government workshops, in prisons, and in other public institutions; upon the recommendation of the Director of Health and the Honorable, the Secretary of the Interior, the use of polished rice in all public institutions is hereby forbidden. All insular, provincial and municipal officials having control of public institutions, such as workshops, prisons, and so forth, are hereby directed to see that the provisions of this executive order are complied with in the institutions under their control.

(Signed) "W. CAMERON FORBES, Governor-General."

The United States Army has issued the following circular:

"I. On the recommendation of the chief commissary of the division, the issue of Saigon rice to Philippine scout organizations will be continued until Aug. 1, 1910, after which time undermilled rice will be issued.

"II. Circular No. 19, these headquarters, May 9, 1910, publishing schedule of interisland transports, is revoked. By command of Major-General Duvall.

(Signed) "LEA FEBIGER,

"Lieutenant-Colonel, General Staff, Chief of Staff."

Unpolished rice has been exclusively used at the Culion since last March, and since that time no cases of beriberi have made their appearance. This is particularly striking in view of the fact that beriberi was almost constantly present from May, 1906, up until the time that the use of polished rice was discontinued.

Beriberi has also been present almost continuously among the scout soldiers of the United States Army, and it will be of interest to note whether the discontinuance of polished rice among them will also stop the incidence of the disease.

The soldiers connected with the constabulary in the years gone by have suffered very little from beriberi. This is attributed to the fact that instead of having polished rice and other rations issued to them by the Government, they receive a cash allowance and are at liberty to purchase their food wherever they desire. The great majority of them are stationed in the provinces and purchase the rice that is pounded out by hand in the native way; the fact that this is not polished would seem to be the reason why the constabulary soldiers have not been affected to any great extent with beriberi.

With a view of reducing the incidence of malaria in the Philippine Islands the Bureau of Health has purchased 2,500,000 five-grain doses of quinine and will issue them gratuitously to persons living in the malarial districts. It will be of interest to note whether this decreases the incidence of malaria.

The cholera situation in the province of Pangasinan remains about the same, but the infection has gained a foothold in a number of new places in Pampanga, Bulacan, Cavite and Rizal Provinces. Manila was infected by a Greek peddler who arrived from the infected town of Dagupan and entered a boarding house in which there were forty inmates. As soon as he showed positive evidences of cholera the remaining boarders fled to many parts of the city, but in many instances, unfortunately, they had already become infected. As a result, there has been an average number of about two cases per day in Manila during the past week.

Dr. H. E. Schiffbauer of the Philippine Medical School is now in Vienna taking a post graduate course in surgery.

Dr. P. K. Gilman, associate professor of surgery at the Philippine Medical School, leaves July 14 for an extended vacation in the United States.

Dr. Louis Schapiro of Washington, D. C., has been appointed a medical inspector of the Bureau of Health.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 11, 1910.

The Clinical Aspects of Arteriosclerosis.—Henry Jackson says that pathologically the changes in the intima are the most prominent features, representing a conservative process, a protective cement, so to speak, to guard against injury of the arterial wall because of the disease in the media; the primary process is found either as a degenerative or as an inflammatory change in the media, or perhaps some defect or strain of the elastic fibers. Councilman makes three divisions. (1) The nodular form, which does not give rise to clinical symptoms. (2) The senile type, with many symptoms probably directly referable to the condition of the arteries, rather local disturbances in the circulation than disease which affects the body as a whole. The arteries feel like broken pipe-stems. The heart is extremely intermittent and irregular, yet does not show the results of heart failure. (3) Diffuse arteriosclerosis which is a disease found especially in individuals otherwise healthy, most common in those of advanced age. In this form of the disease we find the largest hearts. From clinical and experimental observations it seems probable that we must attach greater importance to the rôle of varying toxic processes associated with acute infectious diseases in the etiology of arteriosclerosis. Yet the chief cause probably lies in overeating and consequent gastrointestinal disturbances. From a clinical standpoint the symptoms may be divided into localized symptoms and general symptoms. Of the former probably the most important are those associated with disease of the vessels of the heart. In many cases of sclerosis of the arch of the aorta we find an extension of the process to the valves of the heart resulting in sclerotic changes of the aortic valves. An important local condition of the heart is found in diseases of the coronary arteries. Again, the heart muscle may be seriously affected by localized disease of the arteries. Among the most important symptoms of localized arteriosclerosis are the disturbances of the nervous system, central and peripheral. The heart and kidneys are the most important organs secondarily diseased. One drug he considers of value as a preventive measure, and, perhaps in some cases, as a curative measure, iodide of potash. In recent years there has accumulated evidence that permanent good is accomplished by the high frequency current.

Notes on the Condition Denominated External and Internal Atony, Suggesting Its Association with Tuberculosis.—A. Mackenzie Forbes is inclined to view ordinary round shoulders or stoop as being a manifestation of a laxity of the ligaments and a weakness in which the

dorsal spine becomes kyphotic in shape, and the lumbar spine compensates by assuming the position of lordosis. It is, in fact, his firm belief that it is impossible to get a dorsal kyphosis without a lumbar lordosis. The way to cure stoop is not to attack the shoulders, is not to attack directly the kyphosis, but rather to attack it indirectly by preventing lumbar lordosis, and thus forcing a reduction of dorsal kyphosis, thereby changing the center of gravity. It is only a question of balance. His practice is to get pressure at the anterior abdominal wall in the hope of primarily altering the lumbar curve, and, secondly, through altering the center of gravity, causing a reduction of the dorsal kyphosis or stoop. To do this he makes a light spinal brace, which is somewhat similar to the spinal brace of the late Fayette Taylor. This brace has shoulders and a pelvic band. The shoulder straps are not to hold the shoulders back, but, with the pelvic band, are calculated to form two fixed points of counter pressure at the upper part of the dorsal spine and at the pelvis. This brace acts simply as a vehicle to carry an abdominal apron or support, which is buckled to it, and which can be expected to so control the abdomen of the patient that a lumbar lordosis is straightened out, which straightening is followed by compensatory changes in the dorsal region of the spine. Among the several interesting points about this condition he mentions its association with tuberculosis; it is undoubtedly the cause of pains referred to the back, to the back of the thighs and, in some cases, to the groins and front of the thighs; it is sometimes accompanied by spasm of the erectores, which may be due to an accompanying tuberculosis of the lumbar glands; there is often a prominence of the dorsolumbar vertebræ, suggesting Pott's disease of the spine; a dorsolumbar kypholordosis varying from an "s" shaped curve to a curved upper dorsal and straight anterior slanting dorsolumbar spine; there is probably always a more or less protuberant abdomen; there is possibly a slight rise in temperature, especially in the evening; there is often associated a neurosis. This condition is to be distinguished from Pott's disease of the spine, from sacroiliac disease, from rheumatoid conditions and from tuberculous lumbar glands.

New York Medical Journal, August 13, 1910.

Singultus Gastricus Nervosus.—Anthony Bassler says that singultus, or hiccough, is a symptom expressed as a sound made by the sudden and involuntary contraction of the diaphragm, and the simultaneous contraction of the glottis which arrests the rising air in the trachea. The type he draws attention to is a functional nervous form occurring as a symptom of a neurotic condition of the stomach. He draws attention to the fact that a neurotic condition of the stomach can exist as a manifest clinical entity apart from any association with hysteria or other generally recognized neurological conditions; he reports two clean cut cases of these. In conclusion, he states that true cases of hysteria in which hiccoughing is a feature are not uncommon, and decidedly more numerous than those he describes. But in these, more or less manifestations of hysteria are always present. Whenever there is any doubt regarding the diagnosis, the rather unimportant feature of local and persistent gastric symptoms, together with the fact that hiccoughing hysterics do not show much if any general deterioration in health would be helpful in distinguishing them.

The Clinical Significance of Depression.—George E. Price says that depression is an emotional state which may be either normal or abnormal; normally it is seen as the direct result of certain definite causes (sorrow, disappointment, ill health, or business reverses). Again, it may be temperamental. Many individuals are what might be termed emotionally sensitive. There is also a class of individuals who seem always to live under a shadow; discontented, dissatisfied—the grumblers. In his article Price considers depression chiefly as an abnormal or pathological state, and it may be said to become abnormal when it occurs spontaneously, without adequate external cause. Depression should be considered not psychologically but clinically. Depression is present in such functional neuroses as neurasthenia and hypochondria, and in such mental diseases as melancholia, circular insanity, dementia precox, paranoia, paresis, and senile dementia. In considering these depressive states it is profitable to approach the subject first from the standpoint of age. In infancy and childhood there is no distinctive persistent depression; no true insanity with dejection; yet depression may be present and together with abnormal sensitiveness, introspection, self-consciousness, or self-distrust, may indicate an unstable nervous system and forecast a mental or nervous breakdown later in life. During puberty or adolescence, depression may appear as a symptom of dementia precox, melancholia, or neurasthenia. In early adult life we find melancholy the chief depressive state. Neurasthenia and hypochondria also contribute their quota of cases. As mature adult life is reached, the depression of early paranoia and of paresis is added to that of melancholia, neurasthenia, and hypochondriasis. In middle life, involutional melancholia is the dominating depressive state and, as old age approaches, senile dementia must be added to the already long list. Melancholy is *par excellence* the insanity of depression; yet depression is no more melancholy than is a cough, phthisis. Memory and orientation are preserved. Self-accusation is conspicuous. Early in dementia precox, it is common for the patient to pass through a period of depression, often associated with apprehension, fear, dread, because of the nature of his delusions and hallucinations. The whole picture of dementia precox is colored by confusion. The depression in hypochondria is dependent on the disturbance of the general somatic feeling; in seeking an objective cause such people arrive at faulty conclusions concerning the nature of the condition. Thus a trivial cough becomes a phthisis, and an indigestion, a gastric carcinoma. The neurasthenic's depression is the result of his pathological fatigue. The neurasthenic does not become insane unless there is the additional element of neuropathy.

Innocently Acquired Syphilis.—The following deductions are offered by Walter Brooks Brouner: (1) That syphilis, one of the most contagious infections afflicting mankind, is undoubtedly on the increase as judged by hospital and private practice. (2) That there is woeful ignorance on the part of the public both as regards its origin, its frequency, and its communicability. (3) That many estimable, respectable people acquire this disease innocently and for a long time are unaware of the real nature of their illness. (4) That these innocent victims innocently infect others. (5) That the most frequent source of infection is by using public drinking cups, public towels in bathrooms, and improperly washed cooking utensils, etc. (6) That the use of the common communion cup in public worship should rapidly be done away with and individual communion cups substituted therefor. (7) That the practice of passing around drinking water in public places of amusement should be prohibited by local boards of health, because of the danger of infection that lurks in these drinking cups. (8) That hospitals, dispensaries, and public buildings should not be provided with public drinking cups, but that indivdual paper cups should be provided. (9) That the public should be instructed as to what to demand from their dentists in the way of aseptic instruments. It is, alas! too common a practice for dentists not to pay any attention to the advances made in our knowledge of asepsis. (10) That medical men should ever be on the alert to diagnosticate lues, or syphilis, when present, ever mindful that it is a disease common alike to the prince and the pauper.

Journal of the American Medical Association, August 13, 1910.

Autointoxication and Allied Intestinal Troubles.—Hiram Woods treats of this as a possible cause of certain vascular and functional disturbances of the eye. The lesions of the adnexa which he considers are those of the lids and mucosa. In discussing the etiology of blepharitis he quotes Shoemaker, who presents the clinical conjunctival picture, with a positive autotoxic cause in view. Before attempting to couple the lid and conjunctival disturbances and discussing the possibility of an autotoxic cause, he adds a third class, recurrent circumcorneal injection, recurrent asthenia of the ciliary muscle, spasm of accommodation, and the condition known as hysterical accommodation spasm, or cyclospasm. In considering the pathogenesis, they call it autointoxication, and there are good reasons for so doing. The reason for calling these eye disturbances, associated with various intestinal disorders, "autotoxic," is that they bear a strong similarity to eye troubles of either known general infectious nature, or to those seen in systemic diseases capable of producing toxins. He thinks there is enough association between the eye disturbances named and manifest symptoms of autointoxication from constipation to justify the belief of causative relation. There is reason to think that the same eye troubles can follow intestinal lesions which do not essentially produce toxic products. It seems that the physiologic chemist is not yet in position to help us much in proving the diagnosis, and that until he is we must study these obstinate cases from a clinical standpoint only. If we are ever to explain them or to relieve them, we must view the eye as the receiving as well as the sending end of what we call remote disturbances.

Vein-to-Vein Transfusion of Blood.—George Morris Durrance and Nate Ginsburg consider this subject under the three following headings: (1) The advantages claimed for the arteriovenous method are that sufficient blood pressure is obtained to introduce the blood quickly from the donor into the circulation of the recipient. The blood obtained is richer in oxygen. On the other hand there are disadvantages; the operation itself is beset with many technical difficulties; the size of the vessel can never be determined beforehand; the pressure and volume of the blood-stream, when the arteriovenous method is employed, are sometimes so great as to cause a grave complication, appearing rapidly and frequently proving fatal. In vein-to-vein transfusion, on the other hand, the surgeon is dealing with the superficial vessels, which are easy of access. Moreover, a gradual flow is obtained so that the danger of engorgement and the resulting sudden dilatation of the right heart are avoided. The size of the structures and the ease of access make it a simpler procedure than the arteriovenous method. The principal advantage they claim for the vein-to-vein method of performing transfusion is its simplicity. There is no danger to be considered except the possible one of hemolysis. (2) The indications for employing transfusion. In general, transfusion is employed either to save life or to hasten a patient's recovery. The indications for performing transfusion are therefore as follows: The sudden depletion of the vascular system due to grave accidents, or following operations, as in the case of hemorrhage occurring during the course of typhoid fever; hemophilia, melena, poisoning with carbon dioxide, coal-tar derivatives and other substances characterized by the production of methemoglobin; the pellagra. (3) The contraindications to transfusion. It is of no value in severe infections, in the cachexia of cancer and in tuberculosis. In pernicious anemia and in leukemia, transfusion has disappointed the great expectations which were aroused. This procedure is decidedly harmful in cases of purpura hemorrhagica, and whenever hemolysis is taking place.

Scab Formation in the Nose.—W. Peyre Porcher considers the etiology and prevention of this condition. Among the most prominent factors to which it has been attributed may be mentioned syphilis, inhalation of dust, tuberculosis, anemia, and chlorosis, tobacco and alcohol, hypertrophic catarrh, effects of a previous purulent rhinitis and suppuration of the accessory sinuses of the nose, fatty degeneration of the infiltrated cells, the trophoneurotic theories and penetration of microorganisms, Lowenberg's ozenacoccus, etc. On account of the fact that whenever inflammatory secretions from any portion of the respiratory tract come in contact with the external air, they become coagulated or gummy and finally hardened with more or less fetid odor, it seems evident that the same process occurs in scab formation, and that therefore it is necessary to select some drug which will maintain the fluidity of these secretions. For this purpose the author has chosen iodid of potassium, and such operative measures as would open the accessory sinuses and give free outlet to all inflammatory exudates, pus collections, etc. It is the custom of the author to begin with the administration of 20 drops of the saturated solution of iodid of potassium and run the dose up rapidly until the secretions in the nose become so fluid that the scabs are easily expelled. Many patients absorbed from 600 to 900 grains daily before the nasal secretions would remain fluid, and this without noticeable ill effects; on the contrary, the gain in flesh would be rapid and the improvement in general health marked. He had been informed that as much as 1500 grains a day had been attended with no ill effects. In every case in which he had used these large doses, together with the operative treatment, the scabs had ceased to form.

A Note on the Treatment of Pernicious Anemia.—Alfred C. Croftan expresses himself as inclined to the belief that gastrointestinal disorders in the overwhelming majority of cases usher in this disease and that the definite point of attack in the treatment is the restoration of nutritive equilibrium by artificial means and the prevention, as far as possible, of abnormal or excessive intestinal decomposition. The author's plan of treatment consists in the incorporation of the maximal amount of proteins administered in conjunction with artificial digestants to facilitate their assimilation and absorption. The diet consists in an abundance of meat, fish, eggs, milk, buttermilk, etc., administered in small quantities at frequent intervals, so that the patient receives five or six meals in the course of the day. Attention must be given to individual idiosyncracies. As many as a dozen eggs should be given daily, if possible. The addition of a little alcohol has been found of value. Nourishment per rectum is given in the form of predigested clysmata, together with sodium bicarbonate, a little sodium chloride, and pancreas, with about ten drops of laudanum. To this treatment are added large quantities of hydrochloric acid by the mouth in mucilage water, ten to fifteen drops of strong acid being given fifteen minutes after each meal, and again thirty minutes after each feeding. Rectal clysmata should be given twice daily, or, if rectal irritation results, once daily. To these remedies the author also adds thyroid extract in doses varying from three to five grains of the extract, three times a day by the mouth or with the clysmata by rectum. The patient may receive some arsenic in the beginning in the form of sodium cacodylate dissolved in normal salt solution in the dose of one grain daily administered intramuscularly. Patients treated with arsenic alone never improved materially and this drug was, hence, merely an adjuvant. Iron was not given, as that drug was ingested in overabundance in the meat juices ingested.

The Lancet, August 6, 1910.

Bilharziosis and How to Prevent It.—James F. Allen recapitulates what is known regarding the cause and prevention of bilharziosis. We know that the disease is caused by a parasite which exists in the water of rivers, streams, and ponds; that it enters the body directly from the water by the urethra or anus during long immersion; and that the longer the immersion the greater is the danger of invasion. Brief bathing in infected water either at home or in a river if followed by thorough drying is perfectly safe. The prepuce most materially assists invasion of the urinary tract and circumcision gives comparative protection. The parasite cannot reproduce itself within the human body. If, therefore, precautions are taken to prevent reentry, the disease will not advance, but will slowly recede, so that by a combination of precautions one can finally get rid of it. The proof of the efficacy of this knowledge is that there are no dangerous or fatal cases of bilharziosis in South Africa. The author compares this status of the disease in South Africa with the terrible ravages that it causes in Egypt, and concludes that State instruction in this matter, together wih facilities for infant circumcision, will cause serious and fatal cases of bilharziosis to disappear from Egypt and will make the disease as innocuous and as infrequent in that country as in South Africa.

Heart Puncture.—J. Wallace Milne relates the history of a girl of 20 years, who, after an attack of rheumatic fever, had a mitral bruit, systolic in time, but with no dilatation and no anasarca. A recurrence still further damaged the heart. A short time afterward she had an attack of heart failure which was tided over in the usual way. A few days later a second attack occurred which was not relieved by these expedients, and, as death seemed imminent, the author opened the left median basilic, but no blood flowed. He then cut into the brachial artery above its division into the ulnar and radial arteries, and only a feeble trickle of dark blood flowed. The patient was half conscious and felt no pain, was cyanosed, and the heart was becoming more and more dilated. He could feel no pulse of the temporals over the zygomata. He then selected the fifth intercostal space, close to the left border of the sternum, as being likely to lie over the right auricle, since the distension had been making more and more to the left. Having frozen the spot with ethylchloride he inserted a trocar and cannula of about the size of a No. 3 catheter vertically into the heart. Blood about the color of porter and thick in consistency flowed. He drew off twenty ounces and closed the puncture by acupressure. Almost suddenly the patient revived, became clear and collected and expressed herself as having felt no pain, and as being quite relieved. The venesections began to show blood through their dressings. The patient remained conscious and free from pain for four hours when she died. The position for puncture in such conditions must be a matter for discussion and selection in each case, as the departure from the anatomical point will be constantly different in each instance. If performed to relieve a heart at the crisis of its struggle, say in acute pneumonia, by lessening the weight and volume of blood, it might in many instances preserve life.

The Serum-Diagnosis of Hydatid Disease; Fixation of the Complement.—After reviewing the principal articles which have been published in connection with this subject, Kenneth Eckenstein describes the method which he used in his experiments, and which is analogous to that indicated by Wassermann for syphilis. Five volumes of absolute alcohol is added to one volume of hydatid fluid obtained from a sheep's cyst. After 24 hours in

an ice-chest the precipitate is gotten rid of by centrifugalization; the supernatant liquid is then passed through a filter and evaporated *in vacuo* at 60° C. The residue is taken up with salt solution and titrated. Before using, the antigen must be diluted with salt solution. The correct dilution is found by testing the hydatid fluid with different sera, as is done with the heart extract in the sero-reaction for syphilis. The dilution which the author uses is one in five. Three rows of tubes are required and the unit used is 100 c.mm. In tube 1 are placed one unit of serum, one unit of salt solution (9 per 1,000), and one unit of antigen; in tube 2, one unit of serum and two units of antigen; and in tube 3, one unit of serum and two units of salt solution. The tubes are incubated at 37° C. for about one and one-half hours. One unit, about 5 per cent., washed sheep's corpuscles is added to each tube, and the whole returned to the incubator until hemolysis has taken place in the control tubes. The third tube serves as a control for the hemolytic power of the serum examined. A positive result is obtained when there is no hemolysis in the first or second tubes but hemolysis in the third. From results obtained in the examination of 18 cases the author concludes that fixation of the complement as a means of diagnosis for hydatid disease would appear to be of considerable value, though it may be absent, either because of the particular method adopted, or because the reaction is latent. The reaction has the same value as any other laboratory test in that a positive result is definite, whereas a negative one is difficult to interpret. There is great difference between workers as to which technique is best. The method set forth in this paper was chosen because of its simplicity, and on account of the good results obtained with it for syphilis.

British Medical Journal, August 6, 1910.

Cats as Plague Preventers.—Andrew Buchanan states that some three years ago he prophesied that "A few years hence we shall look on the neglect of the cat as one of the most extraordinary things in the whole history of our inquiries into the plague and its prevention," and that this prophecy is beginning to come true. While the author does not claim that direct infection never occurs, he holds that there is every reason to believe that plague is mainly due to rats. Poison and traps are ineffectual in disposing of the rats, which are sure to return. The theory that the plague is dying out is not sufficiently well founded to warrant any reliance being placed on that hope. In discussing the comparative value of cats and inoculation, the writer points out that the inoculation of the immense population of India every year or every time the plague threatens would be an impossible task at the present time. Although a knowledge of the value of keeping cats is spreading there are many parts of India in which this is not fully understood, and the interval between epidemics should be utilized to impress the people with the fact that no other means of ridding a locality of rats compares with the rat destroyer provided by Nature—the cat.

Treatment of Smallpox in Red Light and in the Dark.—C. H. Würtzen writes that since Finsen described his method of treating smallpox by exclusion of the chemical rays of daylight in 1893, this method has been employed on every occasion in the Oresunds Hospital of Copenhagen. He finds that panes of red glass present a danger in that they do not always exclude the green rays, even when intensive and of a dark red. No pane of glass should be used unless it has been subjected to spectroscopic examination and proved faultless. Since treatment in the dark differs from treatment in red light only by excluding all other rays as well as the chemical ones, no objection can be made against this method. The idea of treatment in the dark is not new, there being reports of cases treated in this way from 1867 to 1871. Seeing that this treatment can be so easily arranged it is indefensible to expose patients in the early stages of the disease to daylight until they can be exposed to red light in a hospital. The writer points out that in making arrangements to exclude light, attention should be given to passages and adjoining rooms, so that in opening the door of the sick-room no light shall be admitted. When it is necessary to use ordinary light it should only come from a stearine candle. In regard to the effect of red light upon the patient they find that, while some are not appreciably influenced, others find it rather unpleasant. It often produces a feeling of heaviness and headache, and is always found exhausting and tiring for reading. They have not noted any mental excitement, as is said to be the case elsewhere. The wearing of green or blue glasses considerably modifies the red light. The smallest amount of daylight should be excluded, and not admitted freely even for the examination of the patient.

Recovery from Apparent Arteriosclerosis.—After outlining the history and condition of this patient, a man of sixty years, which pointed conclusively to the existence of arteriosclerosis, W. M. Crofton describes the treatment that he employed and which seems to have given unusually favorable results. Working on the hypothesis that arteriosclerosis is due in some cases to nutritional disturbances in the artery wall, partly owing to the exhaustion of the vasomotor nervous system, and partly to the lowering of the food-carrying and eliminative powers of the blood, from a diminution of its salt content caused by autointoxication, the patient was given the salts of Trunecek's serum, slightly modified. They were dispensed in the form of tablets, each containing sodium chlorid 0.4 of a gram, sodium sulphate 0.04 of a gram, sodium carbonate 0.016 of a gram, sodium phosphate 0.012 of a gram, magnesium phosphate 0.016 of a gram, and calcium glycerophosphate 0.012 of a gram. The patient took two tablets three times a day, and also a combination of olive oil, iodine, and glycerophosphates. The iodine would relieve arterial spasm and the olive oil would dissolve out any cholesterin which has been said to be deposited in the arterial walls in arteriosclerosis. He also had a brine bath every morning and occasionally a dose of sodium sulphate before breakfast. Under this régime the patient gained rapidly, and at the end of ten weeks was able to take a long walk and to climb a steep hill without undue fatigue or cardiac distress. The patient is at present in good health and able to do his work without fatigue. The interesting question in this case was, what stage of hardening had the arteries reached? It was conceivable that the arteries might recover from the first two stages but not from the third.

Berliner klinische Wochenschrift, July 25, 1910.

The Ehrlich-Hata Remedy in Suspension.—L. Michaelis has sought to mitigate the irritating action of this substance when injected into the buttocks by preparing it in neutral suspension. When injected in a soluble state, as recommended by the discoverers, the solution is either acid or alkaline. When exactly neutralized it is thrown out of solution. The author dissolves the chloride salts of the preparation in hot water, the resulting solution being acid. A little normal soda lye is added to neutralize it, which causes an alkaline solution. Then phenolphthalein is used as an indicator to secure absolute neutralization. Normal acetic acid is added to the alkaline solution until the indicator is completely decolorized. The substance is at the same time thrown out of solution as a fine yellow suspension. A drop or two of the lye is added until the color of the phenolphthalein barely reappears, and the suspension is at once injected. The patient moves his thigh up and down for several minutes and is then placed in bed for two days. The injections are devoid of pain. The rapid disappearance of the symptoms shows that the remedy is as promptly absorbed as when injected in solution. Thus far the author has treated thirty-six cases without a failure. Rest in bed is intended to prevent afterpains and the formation of a sensitive nodule.

Hereditary Syphilis and the Wassermann Reaction.—Mulzer and W. Michaelis sum up their own findings with those of others as follows: Mothers of syphilitic nurslings and newly born invariably give positive reaction, and women who have borne syphilitic children within four years are to be regarded as latent syphilitics. When newly-born infants present no symptoms of the disease they may react negatively soon after birth, but within the first three weeks post partum the reaction changes to positive, usually coincident with the period of eruption. Nurslings with manifest lues react in general in the percentage of adults in the secondary stage (96 per cent. positive). Children over one year old react like nurslings. Latent syphilitic children react in the proportion of adults with early latent syphilis. It seems more difficult to cause the disappearance of the Wassermann reaction through treatment than is the case with adults. Mothers of syphilitic children give a high percentage of positive results (83 per cent.). When syphilitic parents have several children in succession one is finally born with negative reaction, corresponding to absence of symptoms.

Demonstration of Tubercle Bacilli in Acnitis.—Arndt considers the rare form of lesion described originally as miliary or acneiform lupus of the face, and later known as papulonecrotic tuberculide, acnitis, etc. This and similar conditions have been known to be tuberculous, or at least paratuberculous lesions, through a variety of tests; but demonstration of the bacilli in sections has hitherto been effected, as far as the author knows, in but one case of acnitis. As is well known, demonstration of a few bacilli *in situ* in serial sections is most difficult in this entire

class of affections. The author used successfully the antiformin sediment method for control, and this is much more certain in character, but not free from objection, as bacilli might accidentally find their way into the sediment. The lesions examined were pinhead sized and upward. Serial sections, stained with the Ziehl-Neelsen method, showed in addition to the characteristic histological picture discretely situated rods and granules having all the test qualities of tubercle bacilli. The granular form of the bacillus has long been known to occur in lupus vulgaris of the ordinary type. Generally speaking, the bacilli were both extra- and intracellular, being well represented in the giant cells. As long as the parasite can be shown to exist in lesions of this sort, the author contends that the latter should be known as tuberculides, and no longer as paratuberculides.

Recent Surgery of Pulmonary Tuberculosis.—Samson in a joint review of recent literature concludes that artificial pneumothorax gives good results in advanced and even in desperate cases, provided the disease is confined to one side of the chest and the subject has no other tuberculous lesions. Extensive extrapleural thoracoplastic may be indicated where the preceding intervention cannot be carried out, as when extensive pleural adhesions are present. Freund's operation of dividing the prematurely ossified cartilage of the first rib may be carried out in individual cases, but its theoretical soundness is not yet sufficiently established to warrant it being made a procedure of routine.

Deutsche medizinische Wochenschrift, July 21 and 28, 1910.

Myogenous Leucocytosis.—Grawitz sums up an article on leucocytosis of muscular origin as follows: Increased muscular exertion causes an increase in the leucocyte content of the blood in a ratio of from 1:2 to 1:4. This leucocytosis follows promptly upon the exertion, and is produced apparently by the compression of the lymph spaces by the contracting muscles. The object of the increased production of leucocytes must be the disposal of the metabolic products of muscular activity. Hence under tranquil circumstances we may assume that a normal property of the leucocytes is the taking up and transportation of katabolic substances. This is borne out by the fact that after prolonged muscular repose—as on waking in the morning—leucopenia is present. The first manifestation of myogenous leucocytosis is a marked lymphocytosis, which is succeeded by a neutrophile leucocytosis. The lymphocytes, produced in proportion to muscular activity, no doubt constitute a reserve fund for the leucocytosis, being themselves incapable of function. They enter the blood as the latter is becoming surcharged with the chemical products of muscular activity; and as many as are needed become true leucocytes for taking up the latter. The transformation takes place in consequence very rapidly. The author does not believe that myelocytes are to be found participating in this leucocytosis.

Chloroform Addiction.—Storath reports a case of 15-year-old chloroform habit. The subject was a woman, who began the abuse of the drug at the age of 36. It was taken by inhalation, from 20 to 30 gms. pure chloroform daily. Patient was at times in deep narcosis. It was impossible to find any evidence of destruction of the neurons, arteriosclerosis or renal lesions. The woman was a psychopath, suffered from severe hysteria, and had contracted the chloroform habit from using the drug for typical migraine. There was no tendency to increase the daily dose—if anything the patient was more susceptible than the average individual. There were no withdrawal symptoms when the habit was broken off. The leading phenomena presented throughout by the patient were such as might occur in any psychopath, and were not attributable to any specific action of the drug.

Detection of Spermatozoa in Old Stains.—Gasis, working under Prof. Senator's direction, reports the following procedure. He removes a portion of the garment stained, divides it finely, and places it in the maceration fluid (1 or 2 cm.) for from two to five minutes. A glass rod is used for compression. A drop of the fluid is then spread out on a glass slide and dried by flame. This smear is then stained with 1 per cent. aqueous solution of eosin and decolorized with 1 per cent. aqueous solution of potassic iodide until a faint rose-pink shade is produced. The maceration fluid consists of bichlorid of mercury, 1:1,000. If spermatozoa do not become visible, the stained garment is submitted to longer maceration in a larger quantity of the fluid and the centrifuge used, smears being prepared from the sediment, and again stained and examined as before.

Röntgen Cinematography.—Wertheimer refers to a recent highly successful attempt to produce cinematographic demonstration of radiographs. The idea is by no means new, going back as it does to 1897; and the novelty consists in the method by which the successful results were obtained. The discovery was announced last May by Kastle and two others, and is named "bioröntgenography." The first plate is 18 x 24 in shape and there are 13 negatives in a series. Description of the technique is very meager and without illustrations. It will doubtless appear in full elsewhere. The notice consists chiefly of the objects demonstrated which are the respiratory movements and movements of the stomach, especially the latter. The activity of the stomach is shown in health and in certain diseased states.

Technique of the Injection of the Ehrlich-Hata Remedy.—Wechselmann and Lange appear to have arrived independently of and simultaneously with L. Michaelis (see above) at the determination to inject the new preparation in a neutral suspension. They rejected phenolphthalein as an indicator, however, believing it to be destroyed in the reaction. Their original solution of the remedy is made with soda lye. Glacial acetic acid is used for neutralizing, and ordinary litmus paper as an indicator. Methyl alcohol should not be used as a solvent, for it alone can cause amaurosis in the supersensitive, and this might be set down to the remedy itself. The authors recommend as an injection site the region beneath the shoulder blade. The striking action of the remedy is unimpaired by its injection in suspension. It is not denied that both simultaneous and after-pains are still associated with the injection.

Operative Treatment of Cerebral Apoplexy.—Franke believes in early operation for cerebral hemorrhage, for several reasons. First, there is a marked acute intracranial pressure before death ensues in fatal cases, which should be relieved. This must be done promptly. Second, there is always a possibility of saving life; and third, the destruction of brain tissue which results from hemorrhage may to some extent be arrested. The author is aware that these views are not those which are commonly held. For example, it is taught usually that the sudden escape of a large amount of blood damages the brain tissue immediately. Such teachings, however, rest chiefly on a theoretic basis, and cases are upon record which seemingly prove the converse. The author also believes that the effused blood exerts a toxic action during its absorption as well as behaving as a local irritant. The dangers of puncture are not minimized, but there are but five deaths on record in which puncture itself has caused fatal hemorrhage. Nonfatal hemorrhages are naturally of more frequent occurrence. The author believes that by following the Neisser-Pollack technique for cerebral puncture the danger is reduced to a minimum. He is far from claiming that the time has arrived for routine operation. He would for the present limit intervention to the commonest regional type of apoplexy, viz., that in the vicinity of the lenticular nucleus and internal capsule. If the symptoms point with certainty or probability to this localization he would operate—puncture first, and if this failed, trephine. The symptoms of this type of apoplexy are enumerated in great detail for the benefit of the surgeon, who evidently is not supposed to wait for consultation with a neurologist in an emergency procedure.

Paroxysmal Tachycardia in Basedow's Disease.—Bamberger sums up the relationship between paroxysmal and continuous tachycardia in this affection as follows: The former is rare, incidental, but has a definite connection with the essential tachycardia. It appears to be associated at times with certain developments of the disease. Thus it may coincide with the appearance of the exophthalmus or with an attack of tremors. The author does not believe it is of reflex origin, but regards it as proceeding directly from central nervous influence. It has been observed to follow operative procedures, such as thyroidectomy and ligation of the superior thyroid artery. Paroxysmal attacks doubtless exert an unfavorable prognostic influence. The irritable and often dilated heart can hardly fail to be weakened thereby. Several cases are cited in which dilatation of the heart was marked. The paroxysms therefore demand special treatment. Postural and other mechanical resources for slowing the heart are of no benefit. The author knows of nothing better than opiates given by enema. Cardiac stimulants are of no benefit. Valerian and its derivatives and bromides, both in rather large doses, are of some value. Absolute rest in bed and an ice bag over the heart are indispensable. While the above named all aid in cutting short the paroxysms, there is nothing which will relieve them at once.

Book Reviews.

THE PROLONGATION OF LIFE. Optimistic Studies by ÉLIE METCHNIKOFF. The English translation edited by P. CHALMERS MITCHELL. Popular Edition, with an introduction by CHARLES S. MINOT, Professor of Comparative Anatomy in the Harvard Medical School. New York: G. P. Putnam's Sons, 1910.

THERE is nothing on the title page or in the preface of this book which would explain that it is merely a reprint of the volume published three years ago bearing the same title. The fact is simply mentioned that it is a "popular edition," but evidently the imprint is taken from the same plates as the previous one. Professor Metchnikoff's greatest contributions to science are his "Lessons on the Comparative Pathology of Inflammation," published in 1892, and his "L'Immunite," which appeared in 1901. The present work is in reality a study in optimism and an attempt to show that life can be prolonged by ingestion of the Bulgarian bacillus. Professor Metchnikoff is nothing if not an optimist, and as Professor Minot puts it, "One feels that here is a man to whom hope is a habit of mind." One can only hope that the present edition will be widely read by the general reader.

DESIGN IN NATURE. Illustrated by Spiral and Other Arrangements in the Inorganic and Organic Kingdoms as Exemplified in Matter, Force, Life, Growth, Rhythm, etc., especially in Crystals, Plants, and Animals. With Examples selected from the Reproductive, Alimentary, Respiratory, Circulatory, Nervous, Muscular, Osseous, Locomotory, and Other Systems of Animals. By J. BELL PETTIGREW, M.D., LL.D., F.R.S., F.R.C.P.; Laureate of the Institute of France; Chandos Professor of Anatomy and Medicine in the University, St. Andrews; Fellow of the Royal Botanical, Medico-Chirurgical, Royal Medical, Literary and Philosophical, Harveian, and other societies; formerly Dean of the Medical Faculty, University, St. Andrews; President of the Royal Medical and Harveian Societies; Member of the General Council of Medical Education and Registration of the United Kingdom; Examiner in Anatomy at the University, Glasgow, and in Physiology at the Royal Colleges of Physicians and Surgeons, Edinburgh, etc. Illustrated by nearly 2,000 figures, largely original and from nature. In three volumes. London, New York, Bombay, and Calcutta: Longmans, Green & Co., 1908.

THIS magnificent work consists of three handsome quarto volumes, containing in all some 1,400 pages, with illustrations on almost every page. The title of the work hardly gives a fair idea of its full scope and contents; for although the author has certainly produced the most elaborate and scientific, as well as the latest, contribution to the "argument from design," still the book is not concerned only or even chiefly with this subject (except indirectly). As the author states, "It was necessary to deal with physics, chemistry, botany, zoology, anatomy, physiology, and paleontology more or less in detail, as these all hang together and bear an important relation to each other in such an enquiry as the present." So many topics are introduced, and all of scientific interest, which only bear remotely on the question at issue. The subjects of Animal Locomotion (with which Dr. Pettigrew's name is so intimately associated) and of vertebrate anatomy occupy a large amount of space, and the work as a whole may very fairly be described as a magnificent scientific scrapbook, most skilfully and entertainingly written, of surpassing interest, and of much scientific value.

With regard to "Design in Nature," and his own standpoint in this work, the author says: "In the present work I endeavor to show that the combinations of matter, force, mind, and consciousness are practically endless. I seek to prove that inorganic and organic matter, and physical, vital, and mental force are not opposed to each other; that a Creator, a Prime Mover, or First Cause is necessary to produce dead and living matter and physical, vital, and mental force; and that the same laws, to a large extent, dominate all." And again: "The magnitude of the creative acts and the enormous antiquity of the universe conclusively point to the nature of the Being by Whom, and through Whom everything exists. His presence in matter force, force, life, and intellectual manifestations of all kinds can scarcely be gainsaid if the reasoning faculties be allowed free play and the dictates of conscience followed."

The work contains a clear statement of the author's views and a clever marshalling of the opinions of others, and if we cannot admit that the author has proved his contention it is because we feel that the subject is, at present, incapable of proof. The subject of evolution is not without special difficulties of its own; and while we may incline to certain views on the matter it is safest to say with regard to the origin of our present world and its various forms of living beings, "we do not know."

The third volume is devoted entirely to Animal Locomotion; and what the author has to say on flight, and the principles of construction of wings, will have a great interest at the present time. There are three interesting appendices, reprinted from the *Lancet* and the *Quarterly Journal of Science*, on: (1) History of Anatomical Preparation-making as devised and practised by the author at the University of Edinburgh, and at the Hunterian Museum of the Royal College of Surgeons of England. (2) Aerial Locomotion: Pettigrew *versus* Marey. By Professor Coughtrie. (3) Refutation of the claim put forward by the admirers of Leonardo da Vinci to be regarded as the discoverer of the principles of flight. As a frontispiece to each volume there is a handsome portrait of Professor Pettigrew.

ESQUISSES CLINIQUES DE PHYSICOTHÉRAPIE. Traitement rationnel des maladies chroniques. Par le Docteur J. A. RIVIÈRE. Paris: Imprimerie Bouchy et Cie. 1910.

THIS is a book on mechanical methods of therapy. The first eleven chapters treat of the therapeutic methods of applying electricity, air, light, water, heat and movement. The fifteen final chapters treat of infantile diseases, anemia, pulmonary and cardiac conditions, arthritism, neurasthenia, obesity, arterial sclerosis, disturbances of the digestive tract, of the skin, and of the uterus. The volume concludes with an interesting discussion of the effect of psychic treatment upon disease. There are many statements, however, which can scarcely be subscribed to by American medical men of experience—especially the use of manipulation and massage in cancer of the uterus.

PHYSIOLOGY AND PATHOLOGY OF THE SEMICIRCULAR CANALS. By ADOLPH K. IBERSHOFF, M.D. Foreword by ROYAL S. COPELAND, A.M., M.D. New York: Paul B. Hoeber, 1910.

THIS is in reality a publication of notes taken in the Vienna clinics of Dr. Barany and others, relating to recent work on the physiology and diagnosis of diseases of the semicircular canals. It seems to cover the subject sufficiently, although it is not of course at all exhaustive. There are three tables of differential diagnosis that ought to be of assistance,—namely, the differentiation between labyrinthine suppuration and perilabyrinthitis, neuritis of the eighth nerve, and cerebellar abscess.

HANDBOOK OF THE DISEASES OF THE EAR. For the use of Students and Practitioners. By RICHARD LAKE, F.R.C.S., England. With four colored plates and sixty-six original illustrations. Third Edition. New York: Wm. Wood & Co., 1910.

THIS edition does not differ from the preceding ones in any important details, but it has been thoroughly revised and brought up to date, especially as regards recent work on the labyrinth. It is of course merely a handbook on the subject and is not a work of reference. The author's definition of otosclerosis as a "part of the general sclerosis of the submucous tissue of the upper respiratory tract" might be better. He says that this disease is often associated with atrophic rhinitis. The final chapter deals with the influences of middle ear disease on life assurance.

SOME COMMON REMEDIES AND THEIR USE IN PRACTICE. By EUSTACE SMITH, M.D., Fellow of the Royal College of Physicians. New York: Paul B. Hoeber, 1910.

THIS thin little volume describes the use and misuse of several common remedies, somewhat in the style that made Sir Lauder Brunton's work so popular. The author says that tartrate of antimony is an unjustly neglected remedy; it should be given in small doses at frequent intervals. It is indicated in the early stage of bronchopneumonia in children, and in stridulous laryngitis. As a gastric sedative, hepatic stimulant, and in certain inflammatory conditions of the skin he considers it very useful. Oil of turpentine has rendered him good service as a hemostatic in hemophilia and purpura, likewise in colic, thread-worms, and pernicious hiccough. There is an interesting chapter on the action of the alkalies which the author says should be given in moderate dosage and withdrawn when signs of anemia occur. The alkalies are especially valuable in urinary acidity, and may be used in such diverse conditions as acute bronchitis and toothache where the ache is due to the irritation of an exposed nerve by acid secretions. Dr. Smith uses sodium salicylate in the early stage of appendicitis because he thinks many cases of appendix inflammation are in reality of rheumatic origin.

Unsere Schlafmittel, mit besonderer Berücksichtigung der neueren. Bearbeitet von Dr. C. Bachem, Privatdozent für Pharmakologie an der Universität Bonn. Zweite verbesserte und neubearbeitete Auflage. Mit eine Kurve im Texte. Berlin: Verlag von August Hirschwald, 1910.

We are using fewer and fewer drug hypnotics. If we want to know about the latest one, however, we can find a description of it here.

Die Erkennung des Schwachsinns im Kindesalter. Von Prof. Dr. Th. Ziehen, Direktor der Psychiatrischen und Nervenklinik der Kgl. Charité im Berlin. Nach einem Vortrag für Eltern und Lehrer. Berlin: Verlag von S. Karger, 1909.

A small brochure of 32 pages describing various bodily and mental symptoms found in many feeble-minded children, the early recognition of which aids us in diagnosis and proper treatment.

The Pathology of the Living and Other Essays. By B. G. A. Moynihan, M.S. (London), F.R.C.S. Philadelphia and London: W. B. Saunders Co., 1910.

This book is a collection of numerous essays which have appeared in various medical journals from the pen of the author during the last few years. The wisdom of combining them here is manifest and the book in its present form should enjoy wide reading by the profession and especially by surgeons. There are chapters dealing with the operative treatment of obstructive jaundice, on the violation of Courvoisier's law, the surgical treatment of cancer of the rectum, and the surgery of the common bile-duct. The author lays a great deal of stress on securing a satisfactory history, and makes frequent use of the word "anamnesis" to signify the calling to mind again of past incidents in the patient's career almost forgotten. It is interesting to note that references to American surgery are frequent throughout the volume. The book is to be commended for its clearness and dignity of style.

Imagination and Idealism in the Medical Sciences. By Christian A. Herter, M.D. Chicago: Press of the American Medical Association, 1910.

This is a reprint of an address delivered before the students at the New York College of Physicians and Surgeons in September, 1909. Herter points out that medicine is not an exact science, but "fortunately plastic." It progresses by methods not looking to immediate relief of disease, but toward the solution of some insignificant problem. The monograph sketches in brief the work of modern masters in scientific medicine, especially Helmholtz, Pasteur and Ehrlich. Herter warns against assuming an active practice before the youthful physician is ripe for it. He says: "The student physician who waits patiently year by year to strengthen his individual grip on the processes of disease is laying the unshakable foundations of a telling and distinguished career."

Hématolyse et Hématogenèse. Bacteriolyse et Bactériogenèse. Par Dr. G. Froin, Ancien Interne des Hôpitaux de Paris. Paris: G. Steinheil, 1910.

This extremely interesting volume is devoted chiefly to the problems involved in the first of the two titles. After a general discussion of the chemical and biological characteristics of the red cells the author gives an excellent résumé of the present views in the mechanism of immunity. He then takes up the question of the destruction of the red cells as it occurs normally and as the result of toxic influences, and also the nature of the factors controlling the formation and dissolution of the various types of leucocytes under ordinary and pathological conditions. Then follows a chapter in the destruction and proliferation of bacteria gaining entrance to the body, especially as occurring in tuberculosis. Finally there is a discussion of the blood conditions existing in the anemias and leukemias, polycythemia, tumors of the bone marrow, etc. While not exhaustive, the work is a very satisfactory exposition of the present status of knowledge in the fields in question, and its agreeable style makes it very enjoyable as well as profitable reading.

Consumption, Its Prevention and Home Treatment. By H. Hyslop Thomson, M.D. London: Henry Frowde, Oxford University Press, and Hodder & Stoughton, 1910.

It is desirable that every sufferer from tuberculosis, whether having enjoyed the advantages of a course of sanatorium treatment or not, should be carefully instructed as to his conduct, occupation, diet, and recreation before passing out from direct and constant medical supervision. To instruct the sanatorium patient as to his life subsequent to leaving the institution, and to lay out general principles for the tuberculous invalid who of necessity has to care for himself at home, the author has intended this little volume. The brochure has the advantage of brevity and is to the point, considering without technical nomenclature the causes of and precautions against infection from tuberculosis. General principles are laid down as to hygienic and dietetic treatment, applicable to the patient of ordinary intelligence. Special stress is laid upon the desirability of consulting a medical adviser at stated intervals, and whenever a doubt arises as to procedure. Suitable diets are outlined rather too particularly. On the whole, the pamphlet has merit and is unobjectionable, which cannot be said of many similar works directed to the same object.

Die Forensische Blutuntersuchung. Ein Leitfaden für Studjerende, beamtete und sachverständige Aerzte und für Kriminalisten. Von Dr. Otto Leers, Assistent an der königlichen Unterrichtsanstalt für Staatsarzneikunde an der Universität Berlin. Mit 30 Figuren im Text und 3 Tafeln. Berlin: Julius Springer, 1910.

The demonstration of the presence or absence of blood in suspected spots, etc., is one of the most important problems falling to the medicolegal expert, and often also one of the most difficult. In this little volume Dr. Leers has provided a very comprehensive study of every aspect of the subject, from the macroscopic scrutiny of the spots to the most recent developments of the biological tests, by the precipitin, complement fixation, and anaphylaxis methods. The chemical and spectroscopic tests are described in detail, and the results of these are well illustrated by photographic and colored plates. The descriptions of the technique are sufficiently detailed to serve as working directions, and the book is warmly to be commended to all who are interested in investigations of this sort.

Essentials of Medical Electricity and Radiography. By Edward Reginald Morton, M.D., C.M. (Trin. Tor.), F.R.C.S. (Edin.), Vice-President Electro-Therapeutical Section, Royal Society of Medicine; Lecturer on Radiology, West London Post-Graduate College; Medical Officer in Charge of the X-ray Department, West London Hospital; formerly in charge of the Electrical Department, London Hospital, E. Second edition, revised and enlarged. Chicago: Chicago Medical Book Company, 1910.

The author of this book has attempted to cover in a pocket edition the entire subject of electro-therapeutics and radiography. He has started with the first principles of the physics of electricity and has developed his theme through the many modifications of the constant current, galvanism, faradism, static machines, high frequency currents, and finally a considerable portion of the book is devoted to the *x*-rays. In trying to cover such a large subject in such small space many of the articles are of necessity incomplete. The book, however, only essays to give the essentials of the subject, and this it does in very clear and readable terms. It is written in an especially sane, conservative style, not claiming that electricity is a cureall, nor appealing to mysticism, as is often done in writing upon this subject. While a perusal of the book would not make an electrotherapeutist of the reader, a study of it will be a most useful introduction to larger works on the subject.

Die Zuckerkrankheit und ihre Behandlung. Von Professor Dr. Carl von Noorden, Vorstand der I medizinischen Universitätsklinik in Wien. Fünfte vermehrte und veränderte Auflage. Berlin: August Hirschwald, 1910.

Diabetes is par excellence the disease of which the treatment has been developed on almost mathematical lines, and it is in great measure due to v. Noorden that this has been accomplished. The ability to think of foods in terms of calories is never so essential as in the planning of diabetic dietaries, and the present is an excellent text-book from which to learn the art. In this edition it has been considerably enlarged, and with a number of chapters rewritten, notably those on the physiology and pathology of sugar metabolism, pathological chemistry and metabolism, and the theory of diabetes. In the latter the recent work done in v. Noorden's clinic on the interrelationship of the functions of the chromaffine system and the ductless glands in controlling the sugar metabolism is fully discussed. The chapter on treatment has also been amplified, and the author reemphasizes his former contention that it is necessary to restrict the carbohydrate intake, not only moderately, but as much as possible. The book is the standard treatise on diabetes, and in this edition represents the last word on the disease.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Seventy-eighth Annual Meeting, Held in London, July 26, 27, 28, and 29, 1910.

(Special Report for the MEDICAL RECORD.)

(*Concluded from page 340.*)

SECTION OF GYNECOLOGY AND OBSTETRICS.

Friday July 29—Third Day.

Is It Justifiable to Leave the Other Ovary, if It Appears Unchanged, When Removing a Proliferating Papillary Ovarian Cyst?—Professor NAGEL, Berlin, read this paper. He said that papilloma formed 8 per cent. of all ovarian neoplasms and was unilateral in 33 per cent. of cases. The prognosis as to permanent recovery was good and he had found 83 per cent. alive five years after operation; recurrence in an ovary left behind at a unilateral operation was not frequent; even in carcinoma of the ovary recurrence was not frequent after a unilateral operation, but good statistics were lacking. Cases of pregnancy after unilateral operation for carcinoma and papillary cystoma had been recorded; in two of his own cases both patients were alive seven years after operation and one had had one child and the other three since the operation. From these considerations he concluded that the extirpation of the other healthy ovary was superfluous, especially in young women.

Professor GOTTSCHALK of Berlin had operated on one case unilaterally twenty-one years ago. Since then the patient had married and borne three children and remained quite well. In another case the patient was well eight years afterward, but these cases should be kept under close observation.

Dr. KYNOCH of Dundee in multilocular cyst would not remove other ovary, but in papilloma had seen recurrence in other ovary and he advised bilateral operation except in young women.

Professor SPENCER of London never removed an ovary which appeared to be normal no matter what the condition of the other ovary; he had found papilloma present in 50 out of 200 cases of all kinds of ovarian neoplasms.

Dr. MUNRO KERR of Glasgow pointed out that papilloma varied in malignancy and in undoubtedly malignant cases he would remove both ovaries and uterus.

Dr. W. H. H. TATE of London said that in his experience when there was malignant papilloma of the ovaries both sides were frequently affected and there was ascitic fluid present; this condition rarely occurred under 35 years of age and he always removed both ovaries.

Dr. BLAIR BELL of Liverpool asked what constituted malignancy in a papilloma? As regarded the histology, he considered that definite invasion of the stroma was required to prove malignancy and that alteration in the epithelium was not sufficient. We could not decide from naked eye examination during an operation, but rapid histological examinations of sections while the operation was proceeding might help.

Dr. LOUISE MCILROY of Glasgow had in two cases examined an apparently normal ovary removed at the same operation by the microscope and had found early malignant growth; she agreed with Dr. Munro Kerr that in undoubted cases of malignancy the uterus should be removed as well as both ovaries.

Dr. FELIX MEYER of Melbourne, Australia, had seen recurrence after unilateral operations, had tried making sections at the time of operation and thought that this method gave assistance though it could not be absolutely relied on.

Dr. HAYWOOD SMITH of London asked whether recurrence might not often begin in the stump of the ovary removed at operation?

Dr. SCHARLIEB, the president, said that in 150 cases of ovarian growths she had found 25 malignant and she had learned to regard the prognosis of cystic tumors of the ovaries as much worse than that of uterine fibroids.

Professor NAGEL, in reply, said that he considered that 50 per cent. of papillomatous tumors were malignant.

The Surgical Treatment of Fibrosis of the Uterus.—Dr. LOUISE MCILROY of Glasgow read this paper. She defined the characteristics as uniform enlargement of the organ with a hardened wall, associated with menorrhagia, metrorrhagia, and dysmenorrhea. Some called the condition metritis, others arteriosclerosis. She preferred the term uterine fibrosis. She gave an account of four cases, two of them in unmarried women. She had treated them by curetting, and, when there was marked retroflexion, by ventrosuspension, but with no benefit, and eventually she performed hysterectomy in two of the cases. Microscopic examination showed thickness of the coats of the arteries and fibrosis of the uterine wall.

Dr. TATE of London had seen many cases. He used to treat them all by curetting first, but now in some cases he did hysterectomy without previous curetting; he did not remove the ovaries.

Dr. COMYNS BERKELEY of Middlesex Hospital, London, thought Kelly's operation of removing a wedge-shaped piece of the uterus was a valuable one.

Dr. CURTIS WEBB of London had found good results from zinc-mercury ionization on Massey's method, using a current of 100 milliamperes; the positive pole was applied internally.

Professor SPENCER of London had obtained good results from atmocausis (application of steam to endometrium); mentioned Duhrssen's operation of opening the uterus and removing some of the redundant mucous membrane.

Dr. BLAIR BELL of Liverpool said that the causes of fibrosis were infection, chronic subinvolution, fibrotic changes of menopause. He did not believe that fibrosis ever occurred in young women.

Dr. KYNOCH of Dundee said that in hospital patients who could not afford to carry out palliative treatment hysterectomy was quite justifiable.

Dr. PURSLOW of Birmingham said that he had published in the *British Medical Journal* 12 years ago two of the earliest cases of this disease; he had not met with the condition in nulliparæ; he drew attention to the value of styptol as a uterine hemostatic.

Dr. HASTINGS TWEEDY of the Rotunda Hospital, Dublin, had tried atmocausis in about 12 cases, and had been very pleased with the results. No anesthetic was required, and the operation was quite painless; he applied the steam for 15 seconds and he strongly advised a trial of this method before proceeding to hysterectomy.

Professor GOTTSCHALK of Berlin had obtained good results from rectal injections of gelatin.

The PRESIDENT had seen such cases in young women; would like to try ionization.

Professor DOEDERLEIN of Munich gave a demonstration, by diagrams, of the operations of extraperitoneal cesarean section and hebosteotomy. In the former he made an incision from the pubes to the anterior superior spine parallel to Poupart's ligament, preferably on the right side; he then made a lateral incision in the uterus and extracted the child by forceps; he closed the uterus by continuous suture. In hebosteotomy he made a small incision above pubes, passed the index finger behind the bone, and then, under cover of the finger, passed a needle carrying a Giglis saw and sawed through the bone.

Dr. HASTINGS TWEEDY had done five pubiotomies by this method, but thought that the method of Bumm, in which the needle was passed up behind the bone from below,

without making a preliminary incision, had some advantages; in his cases the patients had been able to walk and to leave the hospital on the 19th day.

Dr. Munro Kerr of Glasgow thought pubiostomy a valuable operation, but considered that it was more difficult than cesarean section. As regarded the so-called extraperitoneal cesarean section, he could not see that it presented any advantages over the usual method.

In answer to a question by Professor Spencer, Professor Doederlein said that the time required from the commencement of the incision to the delivery of the child was 5 minutes.

Intraperitoneal Hemorrhage in Cases of Fibromyoma Uteri.—Dr. A. J. Wallace of Liverpool read this paper. He gave an account of a case under his care in which symptoms came on suddenly, abdominal section was performed, and the blood was found to be coming from a vein on the surface of a subperitoneal fibroid of the posterior uterine wall. Myomectomy was performed. He pointed out that in the recorded cases only once had a correct diagnosis been made before operation.

The Involution of the Puerperal Uterus.—Dr. Nepeau Longridge of Cheltenham presented this communication. He divided the period of involution into two stages, a rapid one lasting one week, in which the uterus lost one-half of its weight, and a slower one lasting six or seven weeks longer. Involution was a process of autolysis and was independent of bacteria; it took place better in an acid medium, and this reaction was present owing to the formation of sarcolactic acid from the muscular action. The uterus was anemic after delivery, and this was shown by the fact that in most mammals, and occasionally in women, there was no lochial discharge whatever. He advised holding the uterus for one hour after delivery, giving ergot, and taking great care that the bladder did not become distended during the puerperium.

Erosion of the Cervix Uteri.—Professor Gottschalk of Berlin gave a lantern demonstration of the pathology of erosion of the cervix. He showed that the normal squamous epithelium was first lifted up by the distended gland follicles beneath it, then it burst and exposed a raw surface beneath. This formed a simple erosion; later the epithelium lining the glands spread out over this surface and thus papillary erosion was formed. Later the stage of healing took place; in this process permanent epithelium grew over the surface and sent deep prolongations downward into the connective tissue, and this growth of epithelium might become malignant. Erosion of cervix was of inflammatory or irritative origin and the normal epithelium was displaced by the distended glands as described above, or by subepithelial hemorrhages; the new surface was covered by the glandular epithelium from the glands, and he was convinced that squamous epithelium was never converted into columnar. He advised excision of the affected area in all severe cases.

This concluded the business of the section. A vote of thanks to the President, Mrs. Scharlieb, M.D., was proposed by Professor Nagel, seconded by Professor Hastings Tweedy, and carried by acclamation.

TROPICAL SECTION.

Human Trypanosomiasis.—A very interesting paper was read by Colonel Sir David Bruce on Trypanosomiasis of Man. He recapitulated the several propositions he laid down at the discussion in this section in 1904 and pointed out that four of them still hold good. At that time he said that as to prognosis, instead of being favorable, as had been stated, there was a mortality of 100 per cent. This is perhaps a controversial point, but in Sir David's opinion, there is no absolute proof of a single recovery. The figures were, that up to the present 49 cases had been recorded among Europeans; of these 28 had died, of 12 there was no reliable record and of the remaining 9 who are still alive, one was attacked 10 years and another 9 years ago and are now reported to be in good health. Notwithstanding this, Sir David expressed his belief rather pessimistically that with only the means at present known to us for its treatment this disease is a mortal one.

An interesting discussion followed the reading of the paper. Dr. Balfour of Khartoum suggested that trypanosome Gambiense underwent morphological changes when passing through other animals such as the mule and in this way modifications might be brought about. He instanced the finding of trypanosome parasites in the blood of American cattle, and the discovery of the resting phases of trypanosomes found in water buck in the Bahr-el-Ghazel province of Upper Egypt. He said that certain oils were found very useful, as "tsetse-fuges," when rubbed into the skin.

Dr. Cook of Uganda gave an instance of the value of atoxyl treatment. Two brothers came to him suffering from trypanosomiasis with the typical glands in the neck; one entered his hospital and underwent regular treatment. The other refused treatment and died in eighteen months, while the former was alive and well at the end of four and one-half years.

He thought there would be great practical difficulty in clearing the lake shore of jungle and bringing it under cultivation and that for some time those engaged in this work would suffer very severely. In his experience the prophylactic treatment of the early stages with arsenic was very hopeful.

Dr. Low remarked that though the trypanosoma found in Rhodesia was not Gambiense yet the various species were much more closely connected than was generally supposed and might be modified by residence in different mammals.

Dr. Prout recounted his experience of sleeping sickness in Sierra Leone and said that there was no doubt that till recently the disease was only sporadic there and he could only find records of three or four cases in the course of twenty-five years: then it was introduced in a virulent form from the Congo and rapidly became epidemic.

Dr. Sambon detailed some experiments made with chopped-up flies and said that the most reasonable explanation of the phenomena was that the Glossina palpalis takes up the parasite in two stages: if the asexual stage then no further development takes place, but if the gametes are taken by the fly then they continue to develop and infect.

Tuberculosis in India.—A paper was read by Lieut.-Col. Roberts, I.M.S., on "Some Features of Tuberculosis in India." He described a form of febrile attack which he called "acute tuberculous fever," which he said was entirely tuberculous in causation, but was often confused with atypical typhoid fever or with simple continued fever. Abdominal symptoms were usually prominent and as the alimentary canal was the seat of most of the lesions it was probable that infection usually occurred through it. There was another kind of tuberculous fever accompanied by enlarged cervical glands. A third variety he described was characterized by continued low fever, the thermometer seldom rising above 100°, and general ill health and debility.

Europeans in the Tropics.—A paper was read by Sir R. Havelock Charles on "Factors Influencing the Suitability of Europeans for Life in the Tropics." The three great requisites for a man or woman going to the tropics were: (1) Even temperament, (2) good digestion, (3) sound nervous system. These might be called the tropical trinity. It was important that the European should have activity without restlessness, energy without impatience, and inflexibility without illhumor. There were three main factors which shortened life and produced ill-

health in the tropics. These were (1) continued high temperature, (2) sudden and great thermal changes, (3) parasitism. It was the nervous system that bore the brunt of unfavorable surroundings and therefore it was of immense importance to investigate the nervous system and nervous history and hereditary taints of candidates with the greatest care. With regard to women, an irritable, changeable, unoccupied woman who was always reading to be amused was not only a danger to herself but a trial and a danger to her husband; on the other hand, the right kind of woman for a wife was the best asset a man could have. Among bars to employment in the tropics he particularly mentioned severe headaches, insomnia, tuberculosis, athlete's heart, arteriosclerosis, chronic looseness of the bowels, habitual drug takers, and anemia. The man who has found his sphere in the tropics "enjoys the good without disdain and endures the bad without impatience." Seventeen members joined in the discussion that followed. All agreed in their testimony to the great strain that residence in the tropics involved on the nervous system. Work was usually strenuous, conditions were adverse, disease rife, and native servants very trying to the temper. For many the strain of having to conduct not only their business but their household management in a foreign tongue was considerable.

Dr. Sambon strongly held to the opinion that if we could get rid of parasitic diseases there was no reason why Europeans should not enjoy as good health in the tropics as anywhere else, but other members did not seem inclined to support him in this.

Dr. Price gave some interesting statistics based on the causes of death or retirement of missionaries. He had tabulated 628 deaths and of these 96 were due to malaria, 65 to enteric fever, 44 to tubercle, 36 to dysentery, 36 to cholera, 36 to blackwater fever, 22 to typhus and 20 to smallpox. Thus 60 per cent. were due to diseases that might be considered preventible. Out of 265 retirements 65 were due to nervous breakdown, 32 to tubercle, 30 to insanity and 14 to debility.

Professor Fülleborn of Hamburg stated that in Germany candidates were tested for their ability to stand large doses of quinine. This plan seemed to commend itself to many of those present.

Dr. Balfour, speaking of functional albuminuria, said it was often benefited by a residence in the tropics and when a candidate was found to have albuminuria it was advisable to use the lactate of calcium test before rejecting him.

Dr. Anderson pointed out that there was immense variety in the climate of the tropics and that some parts were quite suitable to Europeans in general and that by using discrimination suitable climates might be found for many who would be otherwise rejected.

Dr. St. George Grey of West Africa said that when it was necessary to invalid a man home it was essential to have regard to the seasons. Many died by sending them to England at an inclement season who might be saved were they kept at a place like the Canary Islands till a suitable season.

Microplasia.—Professor Fullerborn of Hamburg gave a demonstration of microplasia. He first dealt with methods of staining and then discussed the anatomy of the plasia, illustrating his remarks with a most beautiful series of lantern slides, mostly microphotographs. He discussed his experiments with the mosquito and other biting insects, showed slides demonstrating the development of the malaria parasite, its access to the mosquito and its egress from the same. The speaker discussed how the plasia entered the body, and gave his opinion that it pierced the skin in much the same way as the anmylostoma embryos and was carried into other parts of the body with the blood stream.

Sand-fly Fever.—Colonel Birt then read a paper on phlebotomus or sand-fly fever. In Malta more than 50 per cent. of the troops at one time suffered from this fever during the summer. The greatest incidence was in the month of July. He showed a number of charts serving to indicate the difference in the temperature curve between this and other fevers such as Malta fever and enteric fever. He also showed some specimens of the sand-fly which causes the disease. The breeding places of the insect have been discovered in the interior of old stone walls. The fever has been recorded from Egypt and other countries bordering on the Mediterranean and also from the Panjab.

A few other short papers of less interest were also read.

Museum.—This was an interesting part of the annual meeting and the array of microscopes, each one exhibiting some beautiful and interesting preparation, was imposing. In the tropical section there were microscopical slides showing nearly all the parasites affecting the human body in the tropics, nematodes, insects, protozoa, bacteria, and so on. Most of these were shown in their various stages. There was an interesting series of slides showing the Leishmania tropica of the Oriental sore.

PROCEEDINGS OF THE AMERICAN NEUROLOGICAL ASSOCIATION.

Thirty-sixth Annual Meeting, Held in Washington, D. C., May 2, 3, and 4, 1910.

Morton Prince, M.D., of Boston, President, in the Chair.

(*Concluded from page 258.*)

Wednesday, May 4—Third Day.

Friedreich's Ataxia.—Dr. William G. Spiller of Philadelphia read this paper, saying that the symptoms of this disease had been known many years, but the pathology had been very imperfectly studied. In the case which he reported, in addition to the usual findings in the spinal cord, the peripheral nerves had been greatly degenerated, recent degeneration detectable by the Marchi method had been seen in some of the muscle fibers, and the cerebellar nuclei showed alteration of the nerve cells. Many naked axis cylinders had been detected by the Bielschowsky stain in the columns of Goll, which by the Weingert hematoxylin stain had appeared almost completely degenerated. Dr. Spiller maintained that Friedreich's ataxia was not a degeneration confined to the spinal cord or cerebellum, but was the result of implication of the entire central and peripheral nervous system.

Dr. Sidney I. Schwab of St. Louis asked about the mental status of this case. Was there a suggestion of any syphilitic etiology?

Dr. E. W. Taylor of Boston stated that in one case he had observed post mortem there had been strikingly beautiful degeneration of the cerebellar tract and of Gower's tract, which he had taken to be part of the widespread degeneration throughout the nervous system. He asked whether Dr. Spiller had been able to trace this degeneration of Gower's tract into the cerebellum, and whether anything had been done towards tracing Gower's tract and the cerebellar tract towards their determinations.

Dr. B. Sachs of New York said that to explain hereditary family diseases in connection with the modern laws of heredity the attempt would have to be made some day, and, even though our first steps might be very infantile, we should make a beginning. The distinction between Friedreich's ataxia and amaurotic family idiocy was interesting. That was one point that might be taken up for the starting point of consideration of family diseases. In hereditary ataxia we evidently had an involvement chiefly of tracts of peripheral structures, as Dr. Spiller had so well shown,

and no doubt there was some cellular involvement as well, while amaurotic family idiocy was a purely cellular disease. Some years ago these cases had been spoken of as cases of arrested development. The biologists and sociologists were not satisfied with that, particularly if the symptoms came on later in life, after normal birth, and so on. These family diseases would not occur if there had not been so vital defect in the germ plasm. That vital defect made the organism less resistant to extraneous influences or to influences within the body than it would have been if this vital defect in the germ plasm had not existed. In former days Dr. Sachs had been absolutely opposed to the idea that any family disease could be due to any toxic or infectious agent. He did not believe that any family disease could be due to an extraneous toxic or infectious agent, but an infectious agent that was formed within the body itself was conceivable, particularly if you allowed that the injury done to the germ plasm in the first place made the various structures of the body less resistent to poisons formed within the body itself. That was the one step forward that we were able to take in the matter of explaining some of the family diseases. What its application would be to Friedreich's ataxia he did not know, but would like to insist that we go one step further than such careful anatomical, histological work as that reported this morning, and endeavor to bring into line the various family diseases about which so much was being written and in which all of us were so much interested.

Dr. Spiller, closing, said that the Wassermann reaction had not been taken, but there were no clinical manifestations of syphilis. The pathology showed no round cell infiltration such as is characteristic of syphilis of the nervous system. In reply to Dr. Taylor's question, Gower's tract was not degenerated, although in many cases of Friedreich's ataxia it has been. Cellular changes were not usually found in Friedreich's ataxia according to report. The nucleus dentatus in this case showed decided cellular changes. There were also some changes in the cortex.

Personal Experience with Freud's Analytic Method.—Dr. James J. Putnam of Boston read this paper, saying that its purpose was twofold: first, to indicate the character of the author's own successes and failures in the application of Freud's method of pyscho-analysis; next, to indicate the respects in which that method seems to him of importance and the points of view from which it should be studied. In so far as Freud had shown us a valuable means of studying the processes which go on unconsciously within our minds and the respects in which they lead to traits of character and temperament, it was difficult to see how any one could fail to recognize the importance of his work. Most of the criticism had come from persons who had failed to verify his conclusions. That, however, was a different matter, although in the author's opinion, based upon his own observations, the more carefully and thoroughly the method was applied, the more accurately the conclusions derived from it would be found to coincide with those laid down by Freud and others who had followed in his footsteps. The only personal observations which the reader would present as conclusive were those made on about six cases, studied during the past year. A brief summary was given of certain of these cases with a view of indicating the difficulties which attend the application of the method, whether to the dream life or to the waking life, as well as the character and degree of success obtained in treatment. Incidentally, comparison was made between this and other methods with reference to their relative value. It was obvious that the talents and interests of neurologists were not all of the same sort, and for those to whom the study of the mind in health and in disease appeared the most important portion of the physician's work, the contributions of this new field were of marvelous promise and of immense practical importance.

Dr. George L. Walton of Boston expressed the wish that Dante could open this discussion and let us know whether, when he credited Desire with being the root of all things good and evil, he had in mind unconscious memory pictures, as of dreams, to which branch of the subject Dr. Walton confined himself in this discussion. Without venturing to offer a complete explanation of the dream, he felt justified in assuming that it consisted of a series of concepts previously entertained but newly assembled, succeeding each other, sometimes with lightning-like rapidity. One important difference between these memory pictures and those of the waking life is the inability of the dreamer to measure time and space; but the main distinction lies, perhaps, in the absence of goal ideas and of the power of control which enables us in our waking hours to guide our thoughts more or less successfully in definite channels. The associations by which these pictures are assembled will vary with the individual and be tinged by his emotional tone, but to read into them, however ingeniously, the fulfilment of desires is to strain a point, and to substitute a preconceived notion for the study of facts. Dr. Walton found it hard seriously to discuss Freud's illustrative case of a child of tender years who sleeps in a very large bed and dreams he is in a tight place. This dream Freud explains as the fulfilment of the child's wish to be large, a wish so abundantly fulfilled that he thinks himself so large that even this bed is too small for him. To credit mere memory pictures, distorted at that, with being symbols is unduly to glorify the dream state—he should perhaps rather say unduly to debase it when the symbols are of the character which permeates the works of this author. At the risk of seeming prejudiced, he found himself disinclined further to follow the leader whose book on dreams contains that of a young woman who thinks she holds in her hand a branch of a tree, which is assumed to symbolize an organ from which her thoughts should rather be diverted, and in which it appears that breaking off such a limb represents improper manipulation of that organ. The reproduction of a dream in detail, and its analysis, is not only baffling and valueless, in his opinion, for medical practice, but may be harmful. Sholtze says that children should not be encouraged to relate their dreams for their already fantastic imaginations will thereby be the more led away from the real things of life. Similarly, in the treatment of the psychoneurotic, the desideratum is concentration upon the external and the real. As to the comparison between getting up and doing something and analyzing the dream, it seemed to him that an ounce of Muldoon was worth a pound of Freud.

Dr. Edward B. Angell of Rochester agreed with Dr. Walton. These patients need ruthless treatment. He recalled a patient sent to him whom he required to sit up and every time the doubts came upon her to say out loud, "What a damn fool I am!" Two treatments of that sort served to relieve the whole chain.

Dr. B. Sachs of New York said he desired to be absolutely impartial in this matter, not only out of respect for the reader of the paper, but because personally he had been acquainted with Freud for 25 years, ever since they sat in Meynert's clinic. He would agree with anything of Freud's with special delight if he could have felt that his teachings were absolutely sound. There were several practical reasons why they did not appeal to Dr. Sachs: the first counted least, that is, the length of time the examination took and the smallness of the result. For instance, it had taken six weeks for his assistants to get the history of masturbation which Dr. Sachs said he knew existed when he looked at the boy. That was an enormous waste of time. The most serious objection to the method was that it had had a distinct sexual taint given it. Whether all the channels led up to that special function or not Dr. Sachs did not know, but the sexual taint was most marked. It might be of great interest to the neurologist to find out

that some sexual misconception or some disagreeable sexual thought had existed in that person in early years, but while it might be of great interest to the physician, and while it might not do a woman of 40 any harm to have her psychic analysis made as carefully as Dr. Putnam had performed it, it was Dr. Sachs' firm conviction that we did no good by taking a young woman of 14 to 20 and pushing her thought back on that one sexual mistake, not a conscious sexual mistake, that had been made early in life. He could not see that the therapeutic results had been any better nor had they been arrived at any quicker than by the older methods.

Dr. Charles L. Dana of New York felt that he would welcome any new method that would help us in studying this serious class of cases, especially a method that Dr. Putnam had taken so seriously and found some real good in. Dr. Dana's practical experience had been not only of failure, but often of disaster with Freud's method. Taking the case of well-educated and delicate-minded men or women and making them go through the details of early experiences had sometimes just stirred up a mass of old memories, had thrown them almost into delirium at times. It had often been most unfortunate and he had practically stopped giving any such treatment in cases of at least the more educated, more intelligent type of patient that came to him. In dispensary practice perhaps we could find rather more scope for the method. In the minor cases of this class of psychoneuroses he found that by ordinary methods of treatment, education and modern resources of therapeutics they got well. Dr. Dana always told psychasthenic patients that they would get well and they generally did. It must be remembered that a certain number of cases run a course; they got well whether one did anything or not in one or two years. There was another group of cases, more serious, which dated back to early life; these were serious cases he had not been able to do much with. If this method would successfully help them, it would be of value, but he did not see exactly how the philosophy of the method could explain or help a condition which was essentially constitutional. Instead of the Freud method, the quickest way of getting at the inside of these cases was to do what we practically all tried to do and often succeeded. Dr. Dana took patients of this kind, put them in a private hospital and gave them an intelligent nurse; he went to see them often and sent masseurs whom he knew to be intelligent women or men to give them treatment and by every process that he knew of he became acquainted with their story. In two or three weeks he learned about these patients, he knew their past history and he did not believe one could get as much by the Freud method as by our present method. He thought we had much better methods than that of Freud.

Dr. L. F. Barker of Baltimore said it had been his good or bad fortune to see a good many of these patients in the last few years. Any method which helped us to understand the nature of these cases and treat them successfully should be welcomed. He was very glad indeed that so fine a man as Dr. Putnam should undertake this study, the practical testing of Freud's method. It seemed to him that the method should be tested by a man in whom we had absolute confidence whose ethical nature was such that we could have no doubt of the motives of the study. Dr. Barker thought the method should be carefully tested. It had excited world-wide interest and some of the better psychologists had become very enthusiastic about it. It was too early to say how much good would come of it, but certainly a large amount of new knowledge concerning the psychology of these patients, the psychology of life generally was being derived from these studies. He thought we should separate the method of psycho-analysis from the purely sexual idea. In his experience psychoanalysis had been helpful, especially in extending the anamnesis.

Dr. Charles K. Mills of Philadelphia said that hearing what had been said by Dr. Dana and Dr. Barker so well expressed his own views in regard to that matter that there was little left to be said. He thought we owed a debt to Dr. Putnam for the manner in which he had approached and attempted to develop this subject. However, he was not in accord with Dr. Putnam's views. The reports so far had not been altogether satisfactory. The cures did not seem to be in greater number or better than those obtained by the old methods. There are dangers in this method.

Dr. Hugh T. Patrick of Chicago said that Dr. Putnam's method did not differ so very much from the ordinary methods of pyschoanalysis. It seemed to him that psychoanalysis, or whatever led us to get back to the definite original cause of any phenomenon in the abnormal patient, or the beginning of what had been the series of abnormal phenomena, was a help. What he believed to be distinctly injurious was to encourage the patient to probe when he was alone, without control and without the leading intelligence of his physician, into his past life, because we all know that patients are unable to observe facts without conclusions, to observe phenomena without interpretation, and it was particularly these neurotic, poorly balanced, hypersensitive people who were constantly drawing wrong conclusions. This was distinctly dangerous and it was that particular part of the Freud method with which he was at variance.

Dr. Alfred Reginald Allen of Philadelphia said that one saw cases that had been the rounds, having been treated by neurologists in a routine way and well treated, too, and he tried himself to treat them and failed utterly until he used the Freud probe.

Dr. Augustus A. Eshner of Philadelphia said that it should be borne in mind that these patients were already unduly subjective and introspective, and that care should be taken not to make them more so as a result of a certain form of interrogation. Herein appeared to reside a danger entitled to serious consideration.

Dr. Harold N. Moyer of Chicago announced himself a disciple of Putnam rather than of Freud. Any one who undertook to practice Freud's analysis upon his patients on their first visit to the office would soon have no patients. The older methods were to be adhered to for a certain time. As to the psychoanalysis of impotence the physician who neglected to look for some prostatic trouble or stricture would probably fail. This discussion had brought out so far that the old methods were efficient as a rule, but there was a certain residuum of cases not relieved by ordinary methods and for whom was left us this psychoanalysis. It was a distinct, adequate, efficient method of getting at a few cases that we had not succeeded with before until it was offered to us.

Dr. Philip Coombs Knapp of Boston stated that on the first appearance of Freud's work he began to try Freud's method. There was one radical defect in Freud's general position which had not been touched upon. We saw almost every day cases of nervous disturbance of one sort or another due clearly and confessedly to some pronounced emotional disturbance. The cases improved as the emotional disturbance was put into the background and forgotten. It did not seem always to be a reasonable method of treatment in those cases which were due to a forgotten emotional disturbance to drag that once more into the field and get the patient to dwell upon it. It seemed to him that this was the primary unreasonableness of the views of Freud. There was a tendency to consider the data derived from the psychoanalytic methods as being absolutely accurate, but he had not always found them so.

Dr. Ernest Jones of Toronto said that it was too late to attempt to crush out Freud. The movement had already attained such dimensions that it could only be delayed, it

could not be crushed. There was now a large international society with subsections devoted to it. There were over 200 trained workers in Denmark and Russia and Italy. There were four periodicals devoted to the work, besides the mass of literature that had appeared in the general neurological literature and the movement had attained such dimensions that it had even reached England. It was perfectly easy with such startling principles as Freud formulated to form all sorts of excuses and pretexts which were not based on actual experience which no one in the room had excepting Dr. Putnam. Experience with the method was the only primal solution and the only primary criterion for the truth of these matters.

Dr. James J. Putnam, closing, said that Dr. Freud was one of the ablest and most intelligent physicians in Europe and one of the most honest and conscientious. His whole attitude towards the question had been practically the same as the attitude of the various gentlemen who had spoken to-day. He simply then had taken up the fact which he had not invented, although his view had been called by Dr. Knapp a hypothesis. It had never been a hypothesis. It was a generalization upon the facts which had forced themselves upon his notice. He had taken them up in a thoroughly conscientious way, then dealt with them in an extraordinarily broad and scientific way. He brought them together with a thoroughness which no one can have any conception of. He said there was a great deal of misunderstanding of this sexual questioning. One did not take a young unmarried girl and begin to talk to her about her sexual relations. It would be very extraordinary if any one should do that. The sexual ideas were the ones the patient himself brought out. That Freud had always contended. If one had to summarise the value of this matter from the therapeutic side the only word that fitted the case was education. Dr. Mills had spoken of the cruelty of trying to force patients into reviewing the things of which they were afraid; this would be true without explaining to them the nature of the enemy they had to meet. Of course as regards the length of time to which Dr. Sachs referred that was not a criticism against the method; those who did not choose to spend the time needed not to do so. We all spent vast amounts of time in studying the anatomy of the nervous system and we were now devoting ourselves to this study, to the anatomy of the mind. One was quite as justifiable as the other. Then again the persons who spoke as though the sexual thought were brought out in these patients' minds had failed to recognize that they were suffering from these thoughts and the purpose was not to dwell on sexual thoughts, but to relieve their minds from sexual thoughts which in another form were active aand producing symptoms. As to the objection to the patient's probing himself, it was injurious to him to probe himself alone, and it was to prevent the patient from doing this that the patient was encouraged to probe himself before the physician; the patient probes himself alone from morning to night otherwise, and it was to make it impossible for him to do this that we used this treatment.

The Nature and Conception of Dementia Præcox.—Dr. Adolf Meyer of New York read this paper, saying that Kraepelin had created the picture of dementia præcox under a set principle of nosology, with general paralysis as the paradigma. Each disease had its specific lesion, and a true clinical entity had its unity of cause, course and outcome and was necessarily the clinical picture of a unitary and specific lesion. General paralysis was a specific disease-process best characterized by its lesions and by its definite syphilitic origin; but in dementia præcox the nature of the lesion was not so decisive. The departure of our recent work consisted in the surrender of nosological dogma for greater interest in the dynamic interpretation of the disorders out of the psycho-biological material at hand as preferable to a dogmatic assumption of a hypothetical unitary toxic principle. The studies of metabolism and toxic states so far furnished nothing specific or decisive in regard to dementia præcox. The neurological and histological data appeared rather as incidental to more clearly definable functional data than with a leading rôle. The data of conduct and behavior and of reactive material of the patients had proved much more directly helpful in furntshing constructive materials. The etiological constellations were necessarily complex. According to the make-up, the same results might be reached by combinations of marked constitutional peculiarity and slight external cause, and slight overt constitutional peculiarity and marked external cause. The essential was the break of compensation of mental (chiefly emotional and volitional) adjustment with more or less deficit—and in most cases with the peculiar attempts at balance and reconstruction which constitute the glaring surface-picture of the clinical description and the special mechanism of the analytical consideration. The main question was, of course, whether the psycho-biological estimates made it possible to distinguish differences of individual risks and prognosis, which would be preferable to the wholesale prognostication under an excessively broad disease "entity." Evidence seemed to favor the postulate of a departure from the Kraepelinian dogma. Dementia præcox was essentially unlike general paralysis and more likely the usually inevitable outcome of (1) conflicts of instincts and (2) incapacity for a harmless constructive adjustment.

On Some of the Mental Mechanisms in Dementia Præcox.—Dr. August Hoch of New York read this paper, saying that the topic assigned to him in the symposium was the symptomatology of dementia præcox from the point of view of the content of the psychosis. In certain paranoic states, such as those described by Rudin and Gaupp, also in a certain type of psychosis recently analyzed by Birnbaum, the content of the psychoses represented conflicts and reactions to conflicts which the individual, owing to a constitutional defect, was incapable of handling adequately. The clinical picture of dementia præcox was much more complicated and often presented apparently a disconnected array of manifestations. When it was possible to analyze these, however, it was found that all the experiences meant something to the patient; that certain Freud mechanisms were at work, and that these apparently disconnected symptoms were connected and related to definite trends. The frequency with which sexual conflicts were found in the history of such patients and the fact that so often sexual trends made up the content of the psychosis pointed to a lack of sexual adaptation. Our memories were grouped as it were in more or less extensive and more or less circumscribed complexes or centers of attraction, in the formation and cohesion of which special interests took an important part. We could conceive of the mind therefore as made up essentially of trends of interest. In the course of individual development certain main tendencies of the personality developed which then took the lead, while other tendencies became repressed. These repressed trends exerted nevertheless a marked influence on the conscious thought and activity, as Fred had shown, but in normal life they did so mainly through the fact that the energy they supplied was led into profitable channels. Every trend naturally pushed towards a realization in the direction of its feelings. If this was in harmony with the main tendencies of the personality this was useful and represented the dynamic force behind our thinking and our pursuits, adapted to the environment and the given situation. If, however, trends which were not in harmony with the main tendencies of the personality and which were, therefore, under the influence of repression, no longer found an outlet in profitable channels, but assumed a more or less independent dominating role, it was not to be supposed that the laws which governed nor-

mal mental activity should be suspended; on the contrary, we should expect to find the same principle of the trend pushing towards its realization, while at the same time the other tendencies of the personality asserted themselves in repressing influences as well as in adjustment reactions, but owing to the disturbance of balance between the usurping trend and the main tendencies of the personality the thinking and acting was then no longer adapted to the actual situation, but appeared as something strikingly out of contact with it, and was of a simpler, more crude type. This in so far as the mental side was concerned was what seemed to take place in the cases of dementia præcox which could be analyzed: the overgrowth of certain trends at the expense of the main, adapted interests of the personality.

The Margin of Error in the Diagnosis of Mental Disease: Based on a Clinical and Anatomical Review of 250 Cases Examined at the Danvers State Hospital, Massachusetts, 1904-8.—Dr. E. E. Southard of Boston read this paper, saying that a series of 250 cases of mental disease, with intra vitam diagnoses by several physicians, recorded at the Danvers State hospital daily clinics, 1904-8, had been subjected to anatomical review for the sake of learning where lay the greatest difficulties in diagnosis. Ten cases (4 per cent.) remained both clinically and anatomically obscure. Seven cases (2.8 per cent.) had diagnostic doubts settled after the clinic, either intra vitam or post mortem (one case each of general paresis, cortical arteriosclerosis, cerebral sclerosis with Graves' disease, streptococcus septicemia, epilepsy, streptococcus meningitis, cerebellar abscess). Sixty-six cases (25 per cent.) had been doubtful clinically, but then correct diagnosis had been obtained by one or more diagnosticians in 49 of the 66 (74 per cent.) of the doubtful group. One hundred and eighty-four cases (74 per cent.) were clinically certain, and the clinical diagnoses had been confirmed (or not altered) by autopsy in 163 of the 184 (89 per cent. of the unanimous group). The correct diagnosis had been obtained by one or more diagnosticians in 49 plus 163 = 212 cases in 250 (85 per cent.). The "correctness" of these diagnoses is subject to some reservation, (1) since within the "organic and senile dementia group" differentiation proved difficult, and (2) since anatomical "consistency" often signifies absence of characteristic lesions. The acute psychoses have been reviewed, however, bearing in mind modern views. Several alcoholic cases failed to exhibit striking brain lesions. The majority of the real diagnostic difficulties uncovered by this analysis would appear to require more intensive work in the field of clinical pathology. For such work in psychopathic hospitals, this paper was an appeal.

Dr. Cotton of Trenton said that the question of error was one that was very important and error in diagnosis was one that could not always be averted; however, at Trenton they found that by presenting the cases twice at staff meetings the errors had been reduced very much. At Trenton they took up the cases that come to autopsy, corelated them with the clinical diagnosis, and gave the results for the benefit of the staff. This acted as a stimulus to each man and showed errors, both in physical diagnosis and mental diagnosis. The therapeutics could be improved by having a more correct diagnosis. He knew of nothing more serviceable to clear up diagnosis than lumbar puncture. If we took it up in organic and functional cases that were at all suspicious, the negative findings in everything except general paralysis made it a very important factor in arriving at correct diagnosis.

On the Differentiation of Dementia Præcox and Depressed States by So-called Biological Blood Tests.—Dr. Ellen Corson White and Dr. S. D. W. Ludlum presented this paper, saying that while the Wassermann reaction was of greatest value in differentiating syphilis and non-syphilitic diseases of the nervous system, it did not permit of further differentiation in so-called functional nervous diseases. Recently Much had published a method by which he believed he could differentiate dementia præcox and manic depressive disease from other diseases. The method was based on the inhibiting action of blood serum in cobra hemolysis. His results had not been confirmed by others. The authors briefly stated that they seemed to have been able to differentiate between dementia præcox on the one hand and melancholia on the other. Their method was based on the determination of the fixation of complement of guinea pig serum by the serum of the patient. They found in melancholia that the amount of complement absorbed was very much larger than in all other diseases that they had studied, and also much larger than dementia præcox, in which disease it was approximately normal. They had tested 67 cases of various mental diseases. Thirty-seven melancholics of manic depressive type and involutional forms had so far been decisive and characteristic in all cases examined. They had also found that by carefully standardizing the factors in Much's test it gave a positive test only in dementia præcox. When the standardization was not done, a positive result was often obtained. The syphilitic cases could be separated by the Wassermann reaction and progress in biological tests was making it possible to discover chemical changes in so-called functional diseases.

The Clinical Significance of the Urine in "Nervousness."—Dr. Edward B. Angell of Rochester read this paper, stating that he had noted for a number of years in examination of urine of patients afflicted with "nervousness" that in making the Heller nitric acid ring test there was formed at the junction of the urine and acid a pigment ring which varied in color from bright red to dark brown. Of the chemical nature of this ring he was unable to give any account, but believed he was safe in saying that it probably consisted of some of the organic nitrogen compounds. It was a reaction entirely different from that given by indican or bile, although these substances might be associated. A similar reaction occurred in cases of exophthalmic goiter and in those taking iodide of potash. That it was associated with excessive nitrogen elimination was shown by the fact that it was almost never present on a non-proteid diet. The patients who showed this reaction were those who complained of headache, backache, restlessness, sleeplessness, numbness, and a general depressed feeling, associated with other symptoms generally classed as nervous. If such cases were put on a diet low in nitrogen, led an open-air life, and were given salicylates and alkalies to aid elimination they would be relieved of their symptoms, and at the same time this reaction of the urine would disappear. From two weeks to two months were required for a cure. In obstinate cases a year might be required.

Dr. Edward D. Fisher of New York City said that it seems to him that Dr. Angell had given us a rather easy clinical method of diagnosis. If we could find this ring, as he evidently had found it so frequently, a thing that could be done very readily in our offices, it would aid us at least in determining whether our cases were organic or functional. He would like to endorse very emphatically the point that Dr. Angell brought out, that there was very frequently a physical cause for many mental symptoms. The treatment as he had outlined it was one which he had long carried out in cases of neurasthenia. Now that we had a positive diagnosis of the metabolic changes which were going on we would be encouraged to be more systematic in our medical treatment of these cases.

Radiculitis of Cervical and Brachial Plexuses, Secondary to Pachymeningitis Externa Cervicalis Gummatosa.—Dr. F. W. Langdon of Cincinnati read this paper, stating that the patient in the case he reported was a white man of 33, married, with healthy children. Occupation superintending outdoor work, grading, etc.; had gradually de-

veloped a paralysis of tetraplegic distribution, beginning in the left forearm and hand and extending in the course of fourteen months so as to render useless all four extremities. The upper extremities were flaccid, the lower spastic, with plus knee jerks and Babinski sign. The paralysis was preceded by sharp pains in left neck and face, neck movements were almost abolished—not by paralysis of muscles, but by articular obstruction. Numbness and tingling were extensively distributed over both arms and legs. A smooth, firm, not bony, boss could be felt in the left side of the neck, between the third and fourth cervical vertebræ. The patient was unable to walk without constant danger of falling, and was unable to grasp a pencil with either hand. Vision was good, pupillary changes slight; ocular movements free, with slight nystagmoid jerking on extreme lateral excursion. Some dysphagia at times. No voice or tongue changes. Sensory changes slight, excepting the initial pain in the left neck and face, which was not prominent after the first month. There was a hand-size area of tactile anesthesia over the left thorax and one twice as large over the right abdomen, where temperature sense was disturbed or confused. Diagnosis was made of an exudate (gumma) situated between cervical dura and periosteum enclosing the nerve roots and compressing the lateral columns of cord; a radiculitis and compression myelitis, secondary to pachymeningitis externa. Under mercury by inunction and supporting measures steady improvement occurred and patient was discharged at his own request in 5½ months, having gained 25 pounds in flesh, and the use of all extremities. Three months after discharge from the hospital he resumed his regular occupation. At the present time, about a year after the events just recorded, the patient is perfectly well and able-bodied, can use pick and shovel well whenever necessary, and attends to his full duties in every respect.

Further Observations on the Ocular Changes in General Paresis and Tabes Dorsalis.—Dr. Edward D. Fisher of New York read this paper, stating that the examination of fifty cases of general paresis, both of the tabic and cerebral type, confirmed a statement made in a paper read before the American Medical Association in 1909, that optic atrophy and ocular muscle paralysis were comparatively rare in general paresis as compared to their frequency in tabes, nor again were the muscular paralyses permanent as a rule. Clinically this would seem to mark out the two diseases as distinct. In the fifty cases only two had optic atrophy and none any third-nerve lesion outside of the Argyll-Robertson pupil. In the cerebral type of general paralysis, that is, those cases with exaggerated reflexes, the Argyll-Robertson pupil was often absent in the early stages. Among over 200 cases of general paralysis only one presented a history of tabes extending over a number of years preceding the appearance of mental symptoms together with the lightning pains, crises, and ataxia.

Lenticular Zone and Anarthria.—Dr. Alfred Gordon of Philadelphia read this paper, saying that the anatomico-clinical case which he reported showed that Marie's contention in regard to aphasia could be entirely confirmed by the pathological findings. The destruction of the lenticulocaudate nuclei had been complete, and yet the patient did not present the least indication of anarthria or dysarthria. The speech was clear and distinct. The patient did, however, present a partial word-blindness and partial verbal amnesia—all symptoms of sensory aphasia. The few symptoms of the latter corresponded to Marie's ideas. The conclusion to which his observation led was that, while the so-called lenticular zone of Marie might play a certain rôle in sensory aphasia, its rôle was not considerable. As to its being a center for anarthria, the present case proved that its destruction did not interfere with phonation and articulation of words.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Missouri State Board of Health.

June 13, 14, and 15, 1910.

ANATOMY.

1. Describe superficial and deep palmar arch; how formed? Give landmarks.
2. Name all muscles that elevate the arm at shoulder joint, giving origin and insertion of same.
3. Give minute and gross anatomy of kidneys.
4. Give minute and gross anatomy of pleura.
5. Give origin, ending, branches, and relationship of posterior tibial artery.
6. Describe the tibia, giving points of ossification. With what bones does it articulate?
7. Draw cross section amputation of forearm, middle third, naming structures divided.
8. Give origin, course, exit, and parts supplied by the second pair of cranial nerves.
9. Describe anterior triangle of neck, how formed, giving contents.
10. Describe the spinal column, giving characteristics of vertebra in each division.

PHYSIOLOGY.

1. State the general character and physiological action of the hydrocarbon and albuminoid substances.
2. Give mode of secretion and composition of the gastric juice.
3. Give physiological action of the saliva.
4. Describe the blood and give the composition of the red and white globules.
5. Explain the cause of coagulation of the blood and its usefulness.
6. Give the composition of the urine and state which constituent is the most important.
7. State the most important function of the medulla oblongata as a nervous center, with full explanation of same.
8. Name and give function of first pair of cranial nerves.
9. Give origin and function of fifth pair of cranial nerves.
10. State the general arrangement and function of the sympathetic nervous system.

CHEMISTRY.

1. Describe and state the physical and chemical properties of oxygen.
2. Give the chemical formula for potassium iodide, and state how it is made.
3. Name the four elements known as Halogens, and describe each.
4. Give chemical formula for phenic acid. From what derived? For what purpose used in medicine? Give treatment for toxic dose.
5. Give chemical formula for sulphuric acid. How obtained? Give toxic dose. For what purpose used in medicine?

BACTERIOLOGY.

1. Describe the process of producing diphtheria antitoxin.
2. Give theory of immunity produced by vaccination.
3. What diseases confer immunity by vaccination or innoculation?
4. Give the technique for staining for the pneumococcus.
5. Describe in detail process of finding tubercle bacilli in a specimen of urine.

PATHOLOGY.

1. What is aortic stenosis? Give pathology.
2. What is the pathological condition found in chronic Bright's disease?
3. Give the pathology in specific iritis.
4. What pathological conditions are found in acute catarrhal dysentery?
5. Give pathology of chronic gastritis.

THERAPEUTICS.

1. Name the officinal preparations of opium. Give dose and therapeutic uses.
2. Give the physiologic action and therapeutic uses of colchicum.
3. Give the dose and therapeutic indications for bryonia.
4. Name the officinal preparations and give therapeutic uses of calcium phosphate.

5. Give the dose and therapeutic uses of veratrum.
6. Give the dose, physiologic action, and therapeutic uses of ipecac.
7. Name the officinal preparations, give the dose and therapeutic uses of nux vomica.
8. Give the dose and therapeutic indications for tartar emetic.
9. Give the dose and therapeutic indications for aconite.
10. Name the officinal preparations of cinchona. Give dose and therapeutic uses.

PRACTICE.

1. Give etiology, exciting cause, and treatment of variola.
2. What are the methods of physical diagnosis, and what phenomena are obtained by these methods?
3. Give etiology, symptoms, and treatment of lobar pneumonia.
4. What are the physical signs of incipient pulmonary tuberculosis? What is the treatment?
5. What is the etiology and treatment of typhoid fever?
6. Give the symptoms and treatment of acute bronchitis.
7. What are the symptoms of acute Bright's disease, and how should it be treated?
8. What is a cataract, and how would you treat it?
9. How would you diagnose a case of non-suppurative otitis media? What is the treatment?
10. What are the conditions found in psoriasis? What is the proper treatment for same?

OBSTETRICS.

1. Describe pregnancy from ovulation to maturity of fetus, giving mechanism of delivery in an L. O. A. presentation.
2. Describe placenta prævia, giving varieties, causes, diagnosis, and treatment.
3. Differentiate hand from foot, knee from elbow, shoulder from vertex. Give management of shoulder presentation.
4. Define eclampsia, giving etiology, prognosis, and treatment.
5. When should chloroform be used in labor? Ditto ergot? Give advantages and dangers of each.
6. When should forceps be used? Give manner of applying the same, with mechanism of delivery after application, selecting your own presentation.
7. Differentiate false from true labor pains. Give stages of labor and what occurs during each stage.
8. Describe asphyxia of new born, giving varieties and treatment.
9. Give your method of caring for the new born from birth until it is dressed.
10. Give signs of pregnancy at third and sixth months.

GYNECOLOGY.

1. Define vulvitis. Give varieties, causes, and treatment.
2. Define vaginitis, giving varieties, causes, and treatment.
3. Define menstruation. Name disorders of same, giving usual causes and treatment of each.
4. Define metritis. Give varieties, causes, and treatment of each.
5. Give differential diagnosis in inversion, polypi, prolapsus uteri, and method of treating each.

SURGERY.

1. Give differential diagnosis between brain abscess and brain tumor.
2. Describe an operation for cure of femoral hernia.
3. Give symptoms and treatment of acute osteomyelitis.
4. Give diagnosis between gastric cancer and ulcer.
5. What is the treatment of gunshot wound of the knee from a revolver wound?
6. Give the signs and symptoms of tuberculosis of the kidney.
7. Differentiate between an old dislocation and tuberculosis of hip joint.
8. What is the best treatment for a fracture about the elbow joint? Why?
9. Give signs and symptoms of intussusception.
10. What operation do you consider profitable for removal of prostrate gland? Give reasons.

HYGIENE.

1. Give etiology and prophylaxis of ophthalmia neonatorum.
2. Discuss etiology, prophylaxis and hygienic care of cholera infantum.
3. Name three infections transmitted through air; through water; through food; through insects. Give prophylaxis.
4. Give period of incubation, length of quarantine and hygienic care of the following diseases: Smallpox, scarlatina, diphtheria, measles.
5. Discuss vaccination and antitoxine, giving brief history of each, and value of same.

MEDICAL JURISPRUDENCE.

1. What evidence would you look for to distinguish cerebral concussion from intoxication?
2. What evidences determine a recent from an old cerebral hemorrhage?
3. What is malpractice—civil, and criminal?
4. In case of drowning, how would you determine whether homicidal, suicidal, or accidental?
5. In case of hanging, what circumstantial evidence would you look for, to determine whether the act was homicidal, or suicidal?
6. Where a question arises as to personal identity, in what manner, or by what tests would you determine it?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

MISSOURI STATE BOARD OF HEALTH.

June 13, 14, and 15, 1910.

ANATOMY.

1. The *superficial palmar arch* is formed by the ulnar artery, and is completed by the ulnar artery anastomosing with a branch of the radial (superficial volar or princeps pollicis). It gives off the four digital branches. The surface marking is a line drawn transversely across the palm from a point where the web of the thumb joins the palm. The *deep palmar arch* is formed by the radial artery, and is completed by the radial artery anastomosing with a deep branch of the ulnar. Its branches are the palmar interosseous, perforating, and palmar recurrent arteries. The surface marking is a line drawn transversely across the palm, one-half inch nearer the wrist than the superficial arch.

2. Muscles that elevate the arm at the shoulder are: Deltoid and supraspinatus.

DELTOID. *Origin:* From the outer third of anterior border and upper surface of the clavicle, from the outer margin and upper surface of the acromion process, and from the lower edge of the spine of the scapula. *Insertion:* Into the deltoid impression on the middle of the outer side of the shaft of the humerus.

SUPRASPINATUS. *Origin:* From the supraspinatus fossa and fascia. *Insertion:* Into the great tuberosity of the humerus.

3. See Cunningham's "Anatomy" (1909), pages 1130 and 1138; or Gray's "Anatomy" (1908), pages 1419, 1423, and 1426.

4. See Cunningham's "Anatomy" (1909), page 977; or Gray's "Anatomy" (1908), pages 1391 and 1395.

5. The *posterior tibial artery* is the continuation downward of the popliteal artery. It begins at the lower border of the popliteus muscle; it ends midway between the internal malleolus and the tuberosity of the os calcis, where it divides into the external and internal plantar arteries. Its *branches* are: Peroneal, nutrient, muscular, cutaneous, communicating, internal calcanean, and malleolar cutaneous. *Relationships. In front:* Tibialis posticus, flexor longus digitorum, tibia, and ankle joint. *Behind:* Skin, fascia, gastrocnemius, soleus, posterior tibial nerve, and abductor hallucis. *On inner side:* Posterior tibial nerve, at upper part. *On outer side:* Posterior tibial nerve, at lower part.

6. See Cunningham's "Anatomy" (1909), pages 230 and 234; or Gray's "Anatomy" (1908), pages 234 and 238.

7. In amputation of forearm at middle third there will be severed: Skin, fascia, supinator longus, extensor carpi radialis longior and brevior, extensor communis digitorum, extensor carpi ulnaris, supinator brevis, anconeus, pronator radii teres, flexor carpi radialis, palmaris longus, flexor sublimis digitorum, flexor carpi ulnaris, flexor profundus digitorum; arteries; anterior interosseus, radial, ulnar; veins; radial, interosseous, ulnar, median; nerves: posterior interosseous, radial, median, ulnar; bones: radius, ulna.

8. See Cunningham's "Anatomy" (1909), page 675; or Gray's "Anatomy" (1908), page 1038.

9. The ANTERIOR TRIANGLE OF THE NECK is *bounded:* In *front* by a line from the chin to the sternum; *behind* by the anterior margin of the sternomastoid; *base* is upward, and is formed by the lower border of the body of the

lower jaw and a line from the angle of the jaw to the mastoid process. It is *divided* into three smaller triangles (inferior carotid, superior carotid, and submaxillary) by the digastric muscle and the anterior belly of the omohyoid. *Contents:* Thyroid gland, trachea, larynx, parotid and submaxillary glands. Arteries: Inferior thyroid, common carotid, internal carotid, external carotid, superior thyroid, lingual, facial, ascending pharyngeal, occipital, submental, and mylohyoid. *Veins:* Inferior thyroid, internal jugular, lingual, facial superior thyroid, pharyngeal, external jugular, and anterior jugular. *Nerves:* Pneumogastric, recurrent laryngeal, descendens noni, communicans noni, superior laryngeal, external laryngeal, spinal accessory hypoglossal, glossopharyngeal, mylohyoid, and sympathetic. Also lymphatic glands and vessels.

10. See Cunningham's "Anatomy" (1909), pages 75, 78, 81, 83, and 88; or Gray's "Anatomy" (1908), pages 48, 49, 53, 56, and 67.

PHYSIOLOGY.

1. *Hydrocarbons* consist of carbon and hydrogen only; as a rule they are not used as food, and have no particular physiological action. The term was often used loosely to denote fats (containing carbon, hydrogen, and oxygen) whose function is to supply heat and energy, and to serve in the nutrition of the nervous system. *Albuminoids* are a miscellaneous collection of proteins which are neither albumins nor proteids; they are generally insoluble in the neutral solvent of the proteins; they are found in connective tissues, cartilage, bone, skin.

2. *Secretion of Gastric Juice:* "The stomach has two secretions, one thick, tenacious, and alkaline—the gastric mucus; the other, thin, acid, and watery—the gastric juice proper. The former is secreted during fasting, while the latter is only secreted when food or fluid enters the stomach. Saliva or alkalies, pepper, alcohol excite the secretion of gastric juice. Their action is reflex; the vagus is probably the afferent nerve, which, acting on the medulla, inhibits the sympathetic and dilates the blood-vessels supplying the glands; the efferent impulses descending along the splanchnics."—(Ashby.)

The *constituents of gastric juice* are: Water, proteid, mucin, pepsin, rennin, hydrochloric acid, salts (sodium and potassium chlorides, and calcium and magnesium phosphates).

3. *The functions of the saliva* are: (1) To moisten the mouth, (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste, (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition, and (6) to change starches into dextrin and sugar.

4. The *blood* is fluid, somewhat viscid, red, specific gravity from 1055 to 1062, alkaline reaction, saltish taste, characteristic odor, variable temperature (average about 100° F.). The *constituents* are plasma and corpuscles. The *plasma* consists of water and solids (proteids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteins, fat, and inorganic salts). The *white corpuscles* consist of water and solids (protein, leuconuclein, lecithin, histon, etc.).

5. The coagulation of the blood is due to the development in it of fibrin. In the plasma a proteid substance exists, called fibrinogen. From the colorless corpuscles a nucleoproteid is shed out, called prothrombin. By the action of calcium salts prothrombin is converted into fibrin ferment, or thrombin. Thrombin acts on fibrinogen in such a way that two new substances are formed; one of these is unimportant and remains in solution; the other is important, viz., fibrin, which entangles the corpuscles, and so forms the clot. Its usefulness is seen in the checking of hemorrhage.

6. *Composition of urine:* Water, urea, uric acid, hippuric acid, xanthin, hypoxanthin, creatin, creatinin, extractives: chlorides, sulphates and phosphates (of sodium and potassium); phosphates of magnesium and calcium; nitrogen, and carbon dioxide. Urea is the most important constituent.

7. The medulla is the seat of several special centers, the most important of which is probably the respiratory center. "The respiratory center is in reality made up of two centers, one for each side, so that, although anatomically connected and ordinarily acting together, yet if one center is broken up, while the respiratory movements on that side cease, those on the other side continue. Besides this double character of the center, each half is made up of an *inspiratory* and an *expiratory* center. The respiratory center is both an *automatic* and a *reflex* center—*i. e.*, it sends out *spontaneously* impulses which result in movements of the respiratory muscles, constituting its *automatism;* and it may also be excited *reflexly*—*i. e.*, by impulses reaching it from without. Its reflex character is most marked, and it is doubtless as a reflex center that its function is ordinarily performed."—(*Raymond.*)

8. Olfactory nerves; function is special sense of smell.

9. TRIFACIAL NERVE. *Origin:*—(1) *Superficial,* from the side of the pons varolii; (2) *Deep* (sensory root), from the medulla, and upper part of cord; (motor root) from floor of fourth ventricle, and side of the aqueduct of Sylvius.

Functions: First ophthalmic branch supplies sensation to conjunctiva and skin of upper eyelid, cornea, skin of forehead and nose, lachrymal glands, mucous membrane of nose. *Second, or superior maxillary branch,* supplies sensation to skin and conjunctiva of lower lid, nose, cheek, upper lip, upper teeth and alveolar processes, and palate. *Third, or inferior maxillary branch,* supplies sensation to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower teeth, lower lip, and skin of the lower part of the face. This branch, in addition, supplies motion to the muscles of mastication (masseter, temporal, external pterygoid, internal pterygoid), also mylohyoid and anterior belly of digastric.

10. *"The sympathetic nervous system consists of* (1) a series of ganglia connected together by a great ganglionic cord, the gangliated cord, extending from the base of the skull to the coccyx, one gangliated cord on each side of the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three great gangliated plexuses or aggregations of nerves and ganglia, situated in front of the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of smaller or terminal ganglia, situated in relation with the abdominal viscera; and (4) of numerous fibers."

Function: It has a controlling influence over the secretion of most of the glands, the lacrymal, the salivary, the sweat glands, the glands of the stomach and intestines, the liver, the kidney, etc.; it presides over the circulation by regulating the caliber of the blood-vessels and the action of the heart; it influences respiration; and, all involuntary muscles, those of the digestive apparatus, of the genitourinary system, of the hair follicles (pilomotor nerves), are under its control to a great extent.

CHEMISTRY

1. Oxygen is the most abundant of the elements; it occurs free in the air, and in combination in very many substances. It is a colorless, odorless, tasteless gas, slightly soluble in water, heavier than air, combines readily with all other elements except fluorine, supports combustion and respiration, and is necessary to animal life. It has a valence of two, atomic weight of 16, and molecular weight of 32.

2. POTASSIUM IODIDE. *Formula,* KI. *Preparation:* Saturate an aqueous solution of potassium hydroxide with iodine:

$$6KHO + 3I_2 = KIO_3 + 3H_2O + 5KI$$

3. *The four halogens* are: Fluorine, chlorine, bromine, and iodine. *Fluorine* is a very irritant, corrosive gas; it decomposes water, forming ozone and hydrofluoric acid; it attacks organic substances with vigor; it forms compounds with all other elements except oxygen. Valence, one; atomic weight, 19. *Chlorine* is a greenish yellow gas, occurring only in combination. It has a penetrating odor, and is very irritating. It has a tendency to combine with other elements, sometimes with evolution of light and heat. In the presence of water it is an active bleaching and disinfecting agent. Valence, one; atomic weight, 35.5. *Bromine* is a dark, reddish-brown liquid, giving off an irritating vapor. It is only found in combination. It is somewhat similar to chlorine, but less active. Valence, one; atomic weight, 80. *Iodine* is found in combination; is a solid, volatile, its vapor has a violet color and peculiar odor; it is scaly, with metallic luster. It is somewhat similar to chlorine and bromine, but is less active. Valence, one; atomic weight, 127.

4. PHENIC ACID. *Formula:* C_6H_5OH. *Derived from* coal tar. *Used* as an antiseptic, disinfectant; as an application to burns, lupus; as an injection for leucorrhea and gonorrhea in the female; as an antipruritic. *Treatment for toxic dose: Externally,* alcohol; *internally,* sodium sulphate.

5. SULPHURIC ACID. *Formula:* H_2SO_4. *Obtained* by combustion of sulphur, and oxidation and hydration of the resulting sulphur dioxide, by vapor of nitric acid and water. *Toxic dose:* "One dram is the smallest dose reported fatal to an adult. One-half that quantity has caused the death of a child one year old. There is no doubt, however, that as small a quantity as two or three drops of the concentrated acid would prove permanently injurious, while it might not prove fatal. Recovery has taken place after four

ounces when appropriate treatment has been given."—(Riley's *Toxicology.*)

Use in medicine: As a caustic for venereal sores and warts; internally, in serous diarrhea, cholera, acute lead poisoning, and for the night-sweats of phthisis.

BACTERIOLOGY.

1. "Diphtheria antitoxin is obtained from the horse, the animal having been rendered artificially immune by repeated injections extending over a period of several months of gradually increasing quantities of the strongest diphtheria toxin. As the bacilli themselves are not injected, the horse does not become infected with diphtheria, but he gradually acquires a tolerance for the toxins of the disease and develops in his blood a substance (antitoxin) which has the power to neutralize those toxins. At the proper time, when it is thought that his blood has acquired the requisite degree of potency, the animal is bled, and the serum—the part of the blood containing the antitoxin—is carefully separated from the clot, filtered, and standardized. The last procedure is accomplished by determining the quantity of antitoxin serum required to offset the effects of the minimum quantity of toxin necessary to kill a guinea-pig in a definite time. The strength of the antitoxin is measured in units, a unit containing the amount of antitoxin required to save the life of a guinea-pig which has been injected with 100 fatal doses of toxin."—(Stevens' *Materia Medica.*)

2. The introduction into the body of the vaccine is supposed to bring about a reaction, which is evidenced by a marked increase in the bactericidal and agglutinative properties of the blood serum against the particular organism.

3. Smallpox, diphtheria, tuberculosis, bubonic plague, hydrophobia, cholera, typhoid; and it has also been tried in some other diseases.

4. *To stain the pneumococcus:* Spread a cover glass with a smear containing the bacteria, dry it, then fix it in a flame. It can then be stained for from five to ten minutes in Ehrlich's solution; it is then to be washed in water and afterwards immersed in Gram's solution for two or three minutes. It is then washed in 95 per cent. alcohol. While in the Gram's solution the specimen is very dark brown, but it becomes violet or blue again on application of the alcohol.

5. *To find tubercle bacilli in the urine:* The urine should be drawn by a catheter, with the utmost regard to cleanliness and asepsis (so as to exclude the smegma bacillus). The urine thus obtained must be centrifuged for a long time. Some of the sediment is placed on a slide with a small quantity of egg albumin; it is covered with some carbolfuchsin, and allowed to steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin, red rods, while all other bacteria will appear blue.

PATHOLOGY.

1. See French's "Practice of Medicine" (1907), page 588; or Osler's "Practice of Medicine" (1909), page 802.

2. See French's "Practice of Medicine" (1907), pages 898 and 902; or Osler's "Practice of Medicine" (1909), pages 692 and 695.

3. "The iris is congested, swollen, and infiltrated with round cells. There is an exudate of round cells, fibrin, and pigment cells, which fills the anterior chamber and glues the edge of the pupil and back of the iris to the anterior capsule of the lens."—(Alling and Griffin's *Epitome of the Eye and Ear.*)

4. See French's "Practice of Medicine" (1907), page 254; or Osler's "Practice of Medicine" (1909), page 244.

5. See French's "Practice of Medicine" (1907), page 735; or Osler's "Practice of Medicine" (1909), page 466.

THERAPEUTICS.

1. Opium. *Official preparations, with doses:* Powdered opium, gr. j; extract of opium, gr. ss; powder of ipecac and opium, gr. vijss; vinegar of opium, ♏viij; camphorated tincture of opium, 3ij; deodorated tincture of opium, ♏viij; granulated opium, gr. jss; wine of opium, ♏viij; morphine, gr. 1/5; morphine sulphate, acetate, and hydrochloride, each gr. ¼; codeine, gr. ½; codeine sulphate and phosphate, each, gr. ½; apomorphine hydrochloride, gr. 1/10. *Therapeutic uses:* As an anodyne, in diarrhea, peritonitis, for internal hemorrhages, in mania and delirium tremens, in many respiratory affections, in diabetes, and to prevent or lessen shock.

2. Colchicum. *Physiological action:* It is a diuretic, causes irritation of the gastrointestinal tract, salivation, collapse, and increases the output of uric acid. *Therapeutic uses:* Chiefly used in gout; also in headache, dyspepsia, or neuralgia in gouty people.

3. Bryonia. *Dose,* gr. x to lx. It is *used* as a hydragogue cathartic, in cases of dropsy or other serous effusions.

4. Precipitated calcium phosphate, gr. xv; syrup of calcium lactophosphate, 3ij. It is *used* in diseased conditions of the bones, rickets, mollities ossium, scrofula, anemic conditions, tuberculosis.

5. Veratrum. *Dose,* gr. ij. *Uses:* As a circulatory depressant in pneumonia, in puerperal convulsions, tonsillitis, puerperal inflammations in general, mania, and as a rule very much as aconite.

6. Ipecac. *Dose,* gr. j as an expectorant; gr. xv as an emetic. *Action:* Hemostatic, expectorant, emetic, stomachic, cholagogue, and diaphoretic. *Uses:* As an emetic, to clear the respiratory passages, to relieve the stomach, in bronchitis, emphysema, dysentery and jaundice, and as a diaphoretic in rheumatism.

7. Nux vomica. *Official preparations:* Extract, gr. ¼; fluid extract, ♏j; and tincture of nux vomica, ♏x. Strychnine (with its sulphate and nitrate), each gr. 1/64. *Uses:* As a general tonic or bitter; in indigestion, cardiac depression, impaired peristalsis, pneumonia, phthisis, amenorrhea, dysmenorrhea, impotence, and urinary incontinence.

8. Tartar emetic. *Dose,* gr. 1/10 as an expectorant, and gr. ½ as an emetic. *Indications:* In inflammatory affections of the respiratory tract, when the secretion of mucus is not free; in pneumonia, bronchopneumonia, colds, bronchitis, laryngitis, and tonsillitis.

9. Aconite. *Dose:* Fluid extract, ♏j; tincture, ♏x. *Medicinal uses:* For fevers, some inflammatory conditions, in high arterial tension, in nervous palpitation of the heart, and congestive dysmenorrhea; also externally for neuralgia, pruritus, herpes, chilblains, etc.

10. Cinchona. *Official preparations:* Fluid extract, ♏xv; tincture, 5j; compound tincture of cinchona, 5j. Quinine (with its sulphate, bisulphate, hydrobromide, hydrochloride, and salicylate), each gr. iv; cinchonine sulphate, gr. iv; cinchonidine sulphate, gr. iv. *Uses:* In malaria; as a tonic; in influenza, in dyspepsia, in asthma; as an antipyretic; and locally, for sores in diphtheria, and in hay fever.

PRACTICE.

1. See French's "Practice of Medicine" (1907), page 208; or Osler's "Practice of Medicine" (1909), page 112.

2. Methods of physical diagnosis are: Inspection, palpation, percussion, auscultation, mensuration, and weighing. *Inspection* shows the shape, size, symmetry, movements, and color of the chest. *Palpation* confirms and adds to what is learnt by inspection, shows areas of tenderness, condition of chest walls, presence of tumors, action of heart, and the existence and character of fremitus. *Percussion* shows the composition of structures or tissues, the resistance or elasticity or certain organs, and resonance of lungs. *Auscultation* enables one to study the condition of the heart and lungs.

3. See French's "Practice of Medicine" (1907), pages 151, 156, and 174; or Osler's "Practice of Medicine" (1909), pages 165, 172, and 189.

4. The early manifestations of pulmonary tuberculosis are: (1) *Physical signs:* Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist râles at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms:* General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, and night sweats, hemoptysis.

For *treatment,* see French's "Practice of Medicine" (1907), page 392; or Osler's "Practice of Medicine" (1909), page 352.

5. See French's "Practice of Medicine" (1907), pages 65 and 109; or Osler's "Practice of Medicine" (1909), pages 57 and 99.

6. See French's "Practice of Medicine" (1907), pages 649 and 650; or Osler's "Practice of Medicine" (1909), pages 602 and 603.

7. See French's "Practice of Medicine" (1907), pages 893 and 895; or Osler's "Practice of Medicine" (1909), pages 688 and 690.

8. A *cataract* is an opacity of the crystalline lens or its capsule. *Treatment:* Extraction of the lens by operation is the only means of relieving a patient of senile cataract; discission is applicable only to cataracts of the young. No medicinal treatment, whether local or constitutional, is of curative value.

9. See Rose and Carless' "Surgery" (1908), page 882.

10. *Psoriasis* "is a common chronic inflammatory disease of the skin, characterized by variously sized lesions, having red bases, covered with white scales resembling mother-of-pearl. It affects by preference the extensor surface of the body. The lesions are infiltrated, elevated, clearly defined, covered with white, shining, easily detachable scales which, upon removal, reveal a red, punctuate, bleeding surface. The eruption is absolutely dry, and itching is usually absent. *Treatment* consists in the internal administration of arsenic, codliver oil, oil of copaiba, or potassium iodid, and the use of local applications. The scales should be removed by soap and water, alkaline baths, or oily substances. Ointments containing salicylic acid (3 per cent. to 10 per cent.), tar (5i to 5i of ointment), ichthyol (5i to 5ii), chrysarobin (gr. 10-60 to 5i), ammoniated mercury (gr. 10-40 to 5i), etc., are very beneficial, and should be used after the scales have been removed."—(Gould and Pyle's *Pocket Cyclopedia.*)

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), pages 94, 97, 144, and 254; or Hirst's "Obstetrics" (1900), pages 78, 83, and 396.

2. See Williams' "Obstetrics" (1909), page 809; or Hirst's "Obstetrics" (1909), page 572.

3. The *hand* is in a straight line with the forearm, the thumb is at right angles to the other fingers, and may be bent across the palm. The *foot* is at right angles to the leg, the great toe cannot be altered in its relation to the other toes, the malleoli and os calcis may be felt.

The *knee* has two tuberosities with an intervening depression; the patella may also be felt. The *elbow* has three prominences (the olecranon process of the ulna and the two condyles of the humerus).

In *shoulder* cases (as distinguished from *vertex*) the tumor is unsymmetrical in shape, and is longer transversely or obliquely; the head can be felt in one iliac fossa, and the breech higher up in the flank of the opposite side.

In cases of *shoulder presentation*, if seen before labor, version should be performed to correct the malpresentation; in case of impaction a cesarean section is indicated; sometimes decapitation or embryotomy has been performed, but a cesarean section is preferable. Cases of shoulder presentation have been known to terminate spontaneously, but it is not advisable to rely on this possibility.

4. *Puerperal eclampsia* is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death. The *causes* may be: Uremia, albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are renal disease and imperfect elimination by the skin, bowels, and kidneys. *Prognosis* is serious to mother and child. *Preventive treatment:* (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ. *Curative treatment:* (1) Control the convulsions (by chloroform, veratrum, or chloral); (2) eliminate the poison or poisons which are presumed to cause the convulsions; (3) empty the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

5. See Williams' "Obstetrics" (1909), pages 321, 324, 661, and 822; or Hirst's "Obstetrics" (1909), pages 331 and 587.

6. See Williams' "Obstetrics" (1909), page 397; or Hirst's "Obstetrics" (1909), page 809.

7. *False labor pains* are slight, occur before labor, do not cause dilatation of the os, do not produce a "show."

True labor pains gradually increase in frequency and severity, occur during labor, cause the os to dilate, produce a "show."

Labor is divided into three stages: The *first stage* begins with the commencement of labor, and ends with the complete dilatation of the os uteri. The *second stage* begins with a complete dilatation of the os uteri, and ends with the birth of the child. The *third step* immediately follows the second, and ends with the expulsion of the placenta and the beginning contraction of the uterus.

8. See Williams' "Obstetrics" (1909) page 844; or Hirst's "Obstetrics" (1909), page 939.

9. See Williams' "Obstetrics" (1909), page 347; or Hirst's "Obstetrics" (1909), pages 344 and 373.

10. See Williams' "Obstetrics" (1909), page 190; or Hirst's "Obstetrics" (1909), page 204.

GYNECOLOGY.

1. See Rose and Carless' "Surgery" (1908), page 1277. *Varieties of vulvitis:* Catarrhal, follicular, venereal, diphtheritic, and phlegmonous.

2. See Rose and Carless' "Surgery" (1908), page 1277. *Varieties of vaginitis:* Acute, chronic, primary, secondary, catarrhal, membranous, diphtheritic, gonorrheal, granular, emphysematous, and senile.

3. *Menstruation* is a periodical disturbance in the female characterized by a bloody mucous discharge from the uterine cavity; it lasts during the period of woman's sexual activity, but is temporarily suspended during pregnancy and early lactation.

Disorders of menstruation include: (1) Premature or precocious menstruation; (2) protracted menstruation; (3) absence of menstruation (amenorrhea); (4) profuse menstruation (menorrhagia); (5) flow in between periods (metrorrhagia); (6) painful menstruation (dysmenorrhea); (7) vicarious menstruation; (8) regular intermenstrual pain.

AMENORRHEA is *physiological:* Before puberty, during pregnancy and early lactation, and after the menopause. It may also be due to: Absence or imperfect development of the generative organs; also to stenosis, obstructions, or atresia of the genital tract; also to operative removal of the uterus or its appendages. Other causative factors are: Acute infectious diseases, anemia, chlorosis, obesity, drug habits, alcoholism, overstudy, lack of exercise, exposure to cold, and various emotional causes. *Treatment* consists in: (1) Removing the cause, if possible; (2) general treatment by means of proper hygiene, rest, diet, bathing, attention to the bowels, exercise, etc.; (3) drugs reputed to be emmenagogues, such as iron, manganese, aloes, strychnine, apiol, oxalic acid, savine, rue, and tansy.

COMMON CAUSES OF MENORRHAGIA. *Constitutional:* Purpura, scorbutus, hemophilia, hepatic cirrhosis, over indulgence in food and alcoholic drinks. *Local and Vascular:* Uterine congestion and displacement, endometritis, subinvolution, fibroids, and other tumors. COMMON CAUSES OF METRORRHAGIA. *Constitutional:* None. *Local and Vascular:* Disease of uterus or appendages, polyps, extrauterine gestation, the hemorrhages in connection with pregnancy.

TREATMENT OF BOTH: Remove the cause, if possible; treat abnormal conditions that are present; vaginal douches, tampons, and curettage have been recommended; also ergot, hamamelis, hydrastis, and viburnum prunifolium; rest in bed is necessary. Intrauterine applications of astringents or of adrenalin have been used.

DYSMENORRHEA. *Causes:* Pelvic congestion, pelvic inflammation, malnutrition, overwork, lack of development, neuralgia, stenosis or obstruction of the cervix, prolapse or displacement of the uterus. *Treatment:* If possible, remove cause; attend to the general condition, hygiene, tonics, regular habits, etc.; curettage may be necessary, and may have to be repeated (perhaps more than once).

4. METRITIS is inflammation of the body or parenchyma of the uterus. *Varieties:* Acute, chronic, hemorrhagic, catarrhal, suppurative, granular, ulcerative (and also according to etiology). *Causes:* Wounds, injuries, operations, gonorrhea, septic infection, puerperal sepsis, cold during menstruation, intrauterine medication, and manipulations. *Treatment:* Remove the cause, if possible, prevention of sepsis, rest in bed, anodynes, hot vaginal douche, tampons with glycerin, iodin applications, suppository of opium and belladonna, dilatation, curettage, cauterization, irrigation, drainage, etc.

5. In the case of *polypus*, the body and fundus of the uterus are in their normal position in the abdomen, a sound can be passed into the uterus, the uterine and cervical canals are not obliterated, the polypus does not bleed easily, and is not particularly sensible to pain. The *inverted uterus* shows: Absence of body and fundus from normal position, will not permit passage of a sound into uterine cavity, the uterine and cervical canals are absent, the inverted uterus tends to bleed easily, and is very sensible to pain. In *prolapse* the largest part of the tumor is above; the opening of the Fallopian tubes cannot be seen; a sound can be passed into the uterine cavity.

1. SURGERY.

TUMOR OF BRAIN.	ABSCESS OF BRAIN.
1. No primary focus of infection but often history of syphilis or malignant disease of other organs.	1. Suppurating area in ear, nose, pharynx, scalp, or lung abscess.

TUMOR OF BRAIN.	ABSCESS OF BRAIN.
2. Very slow development.	2. More rapid.
3. More definite focal symptoms.	3. Focal symptoms often present, but not so definitely localized as in tumor.
4. No rigors or septic symptoms.	4. Often begins with chills, septic symptoms often continue.
5. Temperature normal or slightly and irregularly elevated.	5. Temperature subnormal, other times higher—pus temperature.
6. Pulse slow.	6. Not slow as a rule.
7. Constant headache.	7. Not a constant or prominent symptom.
8. Projectile vomiting frequently present.	8. Not often; vomiting, if present, more frequent and not projectile.
9. General symptoms of pressure progressive.	9. When present, they vary greatly in intensity.
10. Choked disc constant.	10. Not constant.

—(Eisendrath.)

2. See Rose and Carless' "Surgery" (1908), page 1088, or Da Costa's "Surgery" (1908), page 991.

3. See Rose and Carless' "Surgery" (1908), page 574; or Da Costa's "Surgery" (1908), page 442.

4. *Gastric ulcer* is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents show an excess of free HCl.

Gastric cancer does not usually occur before forty years of age, is more common in males, pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

5. See Rose and Carless' "Surgery" (1908), page 243; or Da Costa's "Surgery" (1908), pages 572 and 258

6. See Rose and Carless' "Surgery" (1908), page 1172; or Da Costa's "Surgery" (1908), page 1115.

7. *Tuberculosis of the hip* is characterized by: Mscular spasm, lameness, shortening, atrophy, and swelling. In *congenital dislocation* there is a history of limp since the child began to walk; the trochanter is above Nelaton's line; there is no muscular stiffness, and no limitation of motion at the hip joint.

8. See Rose and Carless' "Surgery" (1908), pages 507 and 513; or Da Costa's "Surgery" (1908), page 497.

9. See Rose and Carless' "Surgery" (1908), page 1121; or Da Costa's "Surgery" (1908), page 838.

10. See Rose and Carless' "Surgery" (1908), page 1220; or Da Costa's "Surgery" (1908), page 1190.

HYGIENE.

1. Ophthalmia neonatorum. *Etiology:* It is due to the gonococcus or some other pyogenic germ; and is produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc.

Prophylaxis: Whenever there is the possibility of infection, or in every case, wash the eyelids of the new-born child with clean warm water, and drop on the cornea of each eye one drop of a 1 or 2 per cent. solution of nitrate of silver, immediately after birth.

2. See French's "Practice of Medicine" (1907), pages 782, 783, and 781; or Osler's "Practice of Medicine" (1909), pages 507, 508, and 509.

3. Three infections *through air:* Tuberculosis, influenza, measles; *through water:* typhoid, cholera, dysentery; *through food:* typhoid, tuberculosis, beriberi; *through insects:* Bubonic plague, malaria, yellow fever. For *trophylaxis* see French's "Practice of Medicine" (1909) or Osler's "Practice of Medicine" (1909), under name of the disease, in the index.

4. See French's "Practice of Medicine" (1907) or Osler's "Practice of Medicine" (1909), under name of the disease, in the index.

5. "The methods used *in the production of antitoxins* were introduced by Behring, who found that by injecting susceptible animals with increasing amounts of extracellular toxin he produced in the blood serum of the infected animal certain changes which made the serum capable of counteracting the same toxin when injected into other animals. . . . In practice, the bacilli are cultivated in bouillon. The cultures are freed from all living bacilli by filtration. The liquid filtrate contains the toxin. This filtrate is injected into healthy susceptible animals, in increasing doses. Usually the horse is used, since large quantities of blood can be drawn from this animal on account of its size, and, moreover, the horse is very susceptible. . . . Eventually enormous doses of toxin are given, and the animal acquires a high degree of immunity. The blood of the animal is withdrawn, taking care to avoid contamination, and the serum allowed to separate in the refrigerator. The serum of the blood is drawn off and constitutes the antitoxin."—(Williams' *Bacteriology.*)

And see above, Bacteriology, 1, 2, and 3; also French's "Practice of Medicine" (1907), article "Serum," in index.

MEDICAL JURISPRUDENCE.

1. In *cerebral concussion:* There is sudden onset; pulse is slow and weak; respirations are shallow, slight, and irregular; there is functional paralysis; and incontinence of urine and feces. In *intoxication* there is gradual onset; full pulse; respirations deep and slightly stertorous; twitching of muscles; no incontinence; the face is flushed, and the odor of alcohol may be on the breath. *Note:* The two conditions may be coincident.

2. A *recent cerebral hemorrhage* has a red color, the coagulum is not very firm. *Later* the color becomes brownish, the coagulum is firmer and more fibrous, and more adherent to brain and dura.

3. Malpractice is a failure on the part of a medical practitioner to use such skill, care, and judgment in the treatment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil* malpractice. But if done deliberately, or wrongfully, or if gross carelessness or neglect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice.*

4. Drowning. *Homicide:* Rare, except in case of infants; there are probably marks of violence on the body, not due to post-mortem factors. *Suicide:* Very common, and when there were motives to suicide, or tendency to the same, suicide would be suspected; as a rule there would be no witnesses. *Accident:* Very common; often witnesses present; proximity of precipice or other dangerous place would suggest accident. It is often impossible to differentiate the three conditions.

5. Hanging: The presumption is in favor of *suicide;* but evidences of great external violence and marks of a struggle or signs of fingers about the throat would point to *homicide;* a position of the body (with hands and feet tied), in which the patient *could not* have put himself, would point to *homicide. Accidental hanging* is rare, and occurs chiefly among children, while playing.

6. *Personal identity* is based on: Deformities, tattoo marks, scars, general appearance, actions, voice, manner of speech, apparent age, figure, size, gait, dress, moles, birth-marks, professional stigmata, handwriting, finger impressions, foot prints, examination of hair, condition of the teeth, color of hair and eyes.

Practical Indications for the Diet of Infants.—Perier and Gaujoux says that the food ration of the infant should bear relation to its weight, its physical development, and its age. It is also necessary to be careful that the infant is not over fed as well as that it has sufficient upon which to grow. Its amount of food should vary with the season, climate, and altitude. It should vary with the condition of every infant, and it is impossible to give fixed rules for all cases, since each case should be individualized. An infant which weighs four kilograms at birth and whose nurse has an abundant supply of milk that is weak should be fed more than the child who is smaller and gets a more nutritious milk. A young infant who is just beginning to nurse should not be allowed to take all the milk from the breasts when it begins to flow. During the first seven days the amount should be increased 10 grams per day. During the first five months it should be increased 10 grams per month. We may gauge the amount of milk that a child can take by multiplying by two the first two figures of its weight in kilograms. Each time that the child nurses he should suck a single breast, leaving the other for the next lactation. We cannot state in minutes the length of time that a nursing period should last. But the child should never be allowed to suck a long time lest he macerate the nipple, and there is danger of his taking too much. The breasts are habitually asymmetrical; this causes variation in the amount and quality of the milk. Sometimes it is necessary to dry up one breast on account of the difference. It is advised to cause the child to nurse first from the smaller breast so as to increase its size by nursing.—*Annales de Médicine et Chirurgie Infantiles.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of August 20, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	677	170
Diphtheria	192	17
Measles	81	5
Scarlet Fever	86	1
Smallpox	—	—
Varicella	19	—
Typhoid Fever	129	12
Whooping Cough	16	9
Cerebrospinal Meningitis	—	3
Malarial Fever	—	—
Totals	1,200	217

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended August 19, 1910.

CHOLERA

		Cases	Deaths
India, Bombay	June 6–12	..	4
Calcutta	June 19–25	..	42
Rangoon	June 26–July 2	..	2
Present, the interior			
Java	July 2	..	..
Batavia	June 26–July 2	60	50
Mainly among natives			
Samarang	July 2	..	Disapp'r'g
Soerabaya	July 2	..	Do.
Persia, Ardabil	July 2	..	Present
Philippine Islands, Manila	June 12–July 2	33	23
Provinces–			
Bulacan	June 12–July 2	182	122
Cavite	June 12–18	1	.
Mountain Province	June 26–July 2	1	.
Nueva Ecija	June 26–July 2	13	6
Pampanga	June 19–July 2	8	6
Pangasinan	June 12–July 2	1,145	878
Rizal	June 12–25	5	3
Tarlac	June 12–18	1	1
Russia, Odessa	July 10–23	132	69
St. Petersburg	July 10–16	58	20
Straits Settlements, Singapore	June 19–July 2	17	24

YELLOW FEVER

Costa Rica, Siquires	July 31	1	1
Ecuador, Guayaquil	July 1–15	9	3
Sierra Leone	General Aug. 1	..	Present

PLAGUE

Argentina, Rosario	Feb. 1–28	1	1
China, Amoy	July 3–9	..	..
Epidemic in the port.			
Hongkong	June 19–July 2	4	4
Swatow	July 5–11	..	..
Still present in vicinity.			
Ecuador, Guayaquil	July 1–15	4	2
India, Bombay	June 6–12	..	53
Calcutta	June 19–25	..	25
Kurrachee	July 3–9	9	10
Rangoon	June 26–July 2	..	42
Malta, Valletta	July 16	1	..
In quarantine station on Comino Island, from s.s. North Wales			
Mauritius	Apr. 1–June 2	10	7
Persia, Bouchir	June 5–25	7	4
Venezuela, Caracas	July 30	1	1

SMALLPOX

Argentina, Rosario	Feb. 1–28	1	1
	May 1–31	2	2
Brazil, Para	July 17–23	11	6

THE CIRCULATION AS A FACTOR WHICH DETERMINES THE EFFECTS OF MICROBIC INVASION.

BY ALEXANDER HAIG, M.A., M.D., Oxon., F.R.C.P. Lond.,

LONDON.

SENIOR PHYSICIAN TO THE METROPOLITAN HOSPITAL AND TO THE ROYAL WATERLOO HOSPITAL FOR CHILDREN AND WOMEN.

WE all know that microbes attack the weak, the young and weak, and the old and weak (*i. e.* those with but little hold on life), and the poorly nourished, whether young or adults, and this among both animals and men.

But what are the factors that lie just beneath this weakness and poor nourishment? I believe that one of the most important of these factors is *slow and defective capillary circulation.* For capillary circulation controls the function, nutrition, and eventually the structure of every cell of the body tissues; it controls the combustion of the body as a whole, what it does with the food it gets, and what it does with the waste products formed in metabolism; it influences the body temperature, and in a word, its life and reaction to surroundings. for combustion is life and life is combustion.

But what underlies slow and defective capillary circulation? Two factors obviously: (1) Obstruction in the capillaries. (2) Deficient *vis a tergo*, heart power. When both (1) and (2) are present together then the capillary circulation is at its worst and the microbes have the most power for harm.

We now know that the one important cause of capillary obstruction is excess of uric acid in the blood stream, and that this, if severe and long continued, may lead to heart failure from overwork accompanied by malnutrition, leading to dilitation and consequent increased intrapericardial pressure, which again result in extremely defective circulation and nutrition, and eventually bring about fatty degeneration of the cardiac muscle. So that (1) is a direct cause of (2), even if (2) is not originally present as the result of congenital defect in the heart (see "Uric Acid in the Clinic," p. 112).

Let us now take the well-known instance of the common cold. It spreads from person to person through a large community. There is clearly some microbic contagion about it. Yet if we watch carefully we shall see that some take it more easily than others, some individuals take it under certain conditions (*e.g.* women during or just after menstruation), and under other conditions the same people are exempt. Some again do not take it at all and are practically always free from either catarrh, bronchitis, or influenza. Still others, who have suffered perhaps for years a perfect martyrdom from catarrh and bronchitis, alter their diet and become less "gouty or rheumatic" as it is termed, and first partially and then completely lose all tendency to suffer from any form of catarrh or bronchitis (*vide* "Ten Years on a Purin-Free Diet," by Coram James, M.R.C.S., L.R.C.P., in "Folia Therapeutica," July 1909, p. 81). The fact that the tendency to gout and rheumatism is lost at the same time as the tendency to catarrh and bronchitis shows that catarrh and bronchitis have a gouty element in them, and are, as I have elsewhere shown,* due to the precipitation of uric acid by cold aided by the growth and activity of a microbe. Rheumatism may also originate in a precisely similar combined activity of cold and microbe, bringing about a precipitation of uric acid.

Now in the case of catarrh we know exactly the conditions under which the microbe can flourish and succeed in producing trouble; and our knowledge gives us complete power either to cure the trouble or to prevent it.

Prevention, as we have just seen, is by alteration of diet which diminishes the supply of available uric acid. Cure is brought about by dissolving out the uric acid and preventing its reprecipitation in the irritated mucous membranes of the air passages. And provided this is done by so simple a substance as bicarbonate of sodium we need not trouble ourselves in the least about the microbe, as it is thereby rendered powerless for further harm, just as it never has any power for harm in those who are moderately uric-acid-free and whose capillary circulation is constantly good (*British Medical Journal*, Vol. I, 1908, "Treatment of Bronchitis by Alkali").

Let us now compare these conditions, which in the case of catarrh are well known, with the less well-known conditions of invasion by other microbes.

In "Uric Acid in the Clinic," pp. 110, 180 and elsewhere I have pointed out that in certain conditions, such as Bright's disease, mental depression, and neurasthenia, microbes both invade the body easily and may produce the most deadly effects; and there is one condition that is common to all the diseases named, and that is slow and defective capillary circulation, generally entailing defective cell-nutrition and combustion throughout the body with corresponding defects of function and sub-normal temperature. Thus an individual, who is to-day strong, well-nourished, and practically immune to microbic attack, may strain or dilate his heart by some violent and unaccustomed exertion, especially if such exertion is undertaken at the beginning of his annual holiday, when he has for weeks been strictly sedentary and perhaps working overtime in order to get away the sooner. In such a case the immediate effect of the heart strain is slowing of the capillary circulation, which, if it were 6-7 half seconds be-

*"The Etiology, Prevention, and Treatment of a Common Cold." Bale and Danielsson, London, 1905. Also "Uric Acid as a Factor in the Causation of Disease," Ed. VII, J. & A. Churchill, London, 1908.

fore the strain, would now be 8-9. This is the result of two causes, (1) the heart strain, (2) the effect of the heart weakness in lowering general metabolism and combustion; with this last down falls acidity so that all his available uric acid is at once passed into his blood producing a severe collemia, a collemia proportional to (1) the severity of the heart strain, (2) the amount of uric acid available; the latter of these would therefore be much less in those who have lived uric-acid-free.

Now as the result of this greatly defective circulation and combustion, microbes can invade with serious results. They are not long in doing this; either through a skin lesion, which under normal conditions would have healed quickly and safely, or in the intestine where defective circulation means defective digestion and absorption of many foods, leaving to the microbes a rich and varied pabulum in which they can multiply practically unhindered. In this latter case the invasion is evidenced by extremely offensive motions, so that nurses are almost driven out of the room of a patient whose motions in health are nearly odorless.

I may remark in passing that the best treatment of this condition is not by intestinal antiseptics, which are very often nearly powerless in such cases, but by anything that will clear the blood of uric acid even for a time and thus remove one of the factors of the slow capillary circulation, *e.g.* calomel or a minute dose of a salicylate which acts as a retentive. But when the heart condition is very bad even complete clearance of uric acid from the blood may not suffice to stop the microbic invasion. In such cases we have very defective digestion and absorption of food with rapid wasting of tissue as a result, the patient losing as much weight, in some cases even more, than in complete starvation, yet food is being plentifully supplied; but its only effect is to add to the intestinal putrefaction and the triumph of the invading microbes.

Further, as also pointed out in "Uric Acid in the Clinic," p. 287, surgeons are not only finding that precisely the same diet which cures in the case of rheumatism and catarrh also greatly improves the chances of good recovery after operations and assists the healing of wounds. Some surgeons are also coming to the conclusion that in those who live naturally, and have thus a normal circulation throughout the body, surgical wounds require no dressings beyond a piece of lint wrung out of boiled water; for these patients provide their own antiseptics in the shape of a free capillary circulation and a free and active tissue combustion and metabolism.

But before going further I must point out, as already shown in the books previously mentioned, that, in relation to the effects of uric acid on metabolism, life is divided into four physiological stages: two of high nutrition accompanied by retention of uric acid in the tissues so that the blood is pretty clear of it, and two of collemia or solution from tissue deposits in which the blood is clogged with excess of uric acid and the capillary circulation is consequently at its worst. And we should expect that it would be during these two latter stages that microbes would be able to invade with the most deadly effect; and this we shall find to be the case in many diseases. Though, of course, where the nutrition of the body has been completely upset *e.g.* by serious injury or previous disease, these physiological stages are also more or less completely upset and the microbes may then invade at any time, for owing to debility, malnutrition, and anemia the capillary circulation is constantly defective. Apart from such violent inversions of physiology the four stages of life are somewhat as follows: The First Retention Stage of rapid growth and development from birth to 14 in girls and 16 in boys; The First Collemic Stage from 14 or 16 to 25; The Second Retention Stage from 25 to 55, the good nutrition, ruddy health and strength of middle life; The Second Collemic Stage from 55 to death, the decline of all nutrition and metabolism. Each collemic stage is to some extent the result of, and consequently proportional to, the previous retention stage; thus the uric acid stored in the first retention stage furnishes the material for the collemia of the first collemic stage, and so on. Doubtless all these stages would be greatly altered and life itself considerably prolonged and modified if all people lived uric-acid-free.

In reference to pulmonary tuberculosis we find in the Second Edition of Allbutt & Rolleston's "System of Medicine," Vol. V, p. 286, "In children the greatest liability coincides with the approach of puberty, the liability beginning rather earlier with girls." We have seen above that the first collemic stage begins rather earlier in girls for reasons that are fully explained in "Uric Acid," Ed. VII, pp. 517, 521. Girls have also another factor which favors defective capillary circulation, namely, weaker muscles, especially weaker heart muscles.

With reference to enteric fever we find in the same "System of Medicine," Vol. I, p. 1098, "Enteric fever occurs much more frequently among the young and adult persons under 35. It is not uncommon in children, but very rare in infants." I may remark also that when it does occur in infants it is usually milder than in older children nearer the dangerous age of puberty. We must bear in mind that, though we can mark out these stages of life fairly accurately, there is in nature quite a slow gradation from one stage to the next following. Thus no doubt the second retentive stage has greater resisting effect at 35 than at 25.

All that we have said of catarrh and bronchitis applies with almost equal force to malaria. Here we have a parasitic disease the fever of which can be easily and quickly reduced by a solvent of uric acid *e.g.* salicylate; and the attacks can be brought to an end altogether by the uric-acid-free diet (see "Uric Acid," Ed. VII, p. 492-494). Catarrh can also be cured by salicylate when dyspnea does not interfere with its action.

Then again certain conditions such as the time of year act in the same way as the stages of life, and tend to favor the attack of a microbic disease at one season rather than another. I would refer to the well-known fact that the Lent term at schools and colleges is the worst in the year for disturbance of routine by the exanthemata; and I have little doubt that this bears a definite relation to the early spring collemia of returning warmth, when the uric acid retained in the cold of winter begins to pass into solution in the blood and block the capillary circulation. A very notable instance of this occurred in London some years ago when the warm, muggy weather suddenly returned at the end of several weeks of severe cold, and at once almost everyone was down with influenza. Influenza again in every way parallels the relation of catarrh, bronchitis, and malaria both to drugs and to the uric-acid-free diet.

Possibly something of the same kind may explain an experience which used to be related by one of my most honored teachers, Dr. Samuel J. Gee, to the effect that he had been for some years House

Surgeon and Registrar at a hospital with fever wards without taking scarlet fever. He then left the hospital for about a year, and on returning as locum tenens for a friend he at once took the disease and had a sharp attack. It seems probable that this very interesting experience stood in relation to summer collemia (as it occurred in July), as well as in relation to his general condition and stage of life, probably near the end of the first collemic stage, the effects of this being increased by prolonged sedentary life in town.

I may mention in passing that, although some of the complications and sequelæ of scarlet fever (*e.g.* arthritis, endocarditis, and Bright's disease) are commonly attributed to microbic activity, in my opinion they are almost certainly due to the amount of uric acid available in the body, for they are, as far as I know, absent or but little marked in those who are moderately uric-acid-free.

Pregnancy affords an interesting and non-seasonal instance of the same thing, for normal pregnancy is a time of increased metabolism and combustion with good nutrition and relatively high urea and acidity; these latter conditions keep the blood clear of uric acid and the capillary circulation is consequently free. Just as the reverse conditions, debility and starvation with low urea and acidity, tend to flood the blood with uric acid, thereby increasing collemia and defective capillary circulation. Now it is a well-known fact that not only do collemic troubles (*e.g.* asthma, migraine, epilepsy) cease to afflict the pregnant, but they also have a considerable relative immunity from the exanthemata, but only so long as the pregnancy is normal and nutrition and circulation are good. In reference to migraine and pregnancy a friend of mine (the late Dr. E. Horder) made a remarkable diagnosis; a married relative wrote to him that her habitual migraine attacks had suddenly ceased, and he replied that she would now want no more headache drugs for nine months. From the fact that the habitual migraine was suspended he rightly diagnosed that she was again pregnant.

The special liability to microbic invasion which follows the termination of pregnancy is well known, and this is accompanied by fatigue, which means heart weakness, and collemia, which entails defective capillary circulation, the latter being increased by the uric acid of the retention during the period of pregnancy. In the case of those nations who live nearly uric-acid-free the second factor and a large part of the first (as fatigue is proportional to the uric acid in the blood) are absent. Parturition is then encountered without the most rudimentary precautions as to hygiene and cleanliness and apparently very often quite without harm. From which we may again infer that the soil in which it can flourish is very much more important than the invading microbe.

In the relation of scarlet fever to tonsillitis (Allbutt & Rolleston, Vol. I, p. 88) we have again probably a relation to the effects of uratic irritation of tissues which is naturally most marked in cold northern climates. And in the alleged absence of chorea from China (see Allbutt & Rolleston, Vol. I, p. 88) and the diminished severity of measles in Ireland (*loc. cit.* p. 65) we may also see relations between disease and local habits in regard to diet and the consumption of uric-acid-containing foods.

The weak and poorly nourished are an easy prey for the microbes because: (1) any available uric acid is in solution in their blood slowing capillary circulation, (2) their muscles are weak, (3) weak heart is an additional cause of a poor circulation, (4) collemia, weak heart, and slow capillary circulation mean poor nutrition of both blood and tissues, and slow and defective functioning throughout the body. For heart failure increases collemia, and collemia in its turn increases heart failure; then heart failure diminishes both appetite and digestive power, and so the downward trend of the whole physiology of the body is continuous and inevitable till some external factor cuts through the vicious circle.

Chronic underfeeding is thus obviously another factor that increases the power of the microbe to work mischief, and this is a very prevalent condition at the present day. Now such a condition of underfeeding verging toward actual starvation is brought about chiefly in two ways, (1) unconscious and unintentional, (2) intentional as the result of ignorance. The first form has been treated of by Dr. Nathan Rosewater under the name of "Disguised Starvation" (*New York Medical Journal*, Dec. 1909); I have met with plenty of it in my own practice. The patient suffers from collemia and collemic fatigue, and being too tired to eat or digest comfortably takes ever less and less food, and so passes into the power of the vicious circle previously mentioned. The second form is the result of what I regard as the erroneous modern teaching with reference to the quantities required; this leads people to take too little food, and thus they eventually land themselves in collemic fatigue with the results above mentioned (see "Uric Acid in the Clinic," pp. 154, 279, and elsewhere). It is easy to recognise these starvation cases, whatever their origin, as they all have a low and falling blood decimal. My rule is that no one who has been three or four years on a correct uric-acid-free diet should have a blood decimal below .85 or .9. Any one who shows such a defective blood decimal under these conditions has either been underfeeding or taking poisons. Weight may or may not be lost to any great extent, but a low and falling blood decimal renders it advisable to estimate both food and urea from day to day to see that sufficient proteid is being taken and digested. Paradoxical as it may seem, the fact nevertheless remains that up to a certain point the more you eat the more appetite you have, because increased food means increased power of digestion; conversely the less you eat the less appetite you have, because diminished food means diminished power of digestion, and appetite is under all circumstances an index of digestive power.

We see then that there are all gradations from conditions in which microbic invasion is a most serious matter to those in which it is of no consequence. And the one factor that alters in a given individual in the change from one condition into the other is the capillary circulation. When microbes can invade with deadly effect the capillary circulation is always slow; when they are powerless for harm it is always normal or quick. We can now see that the fever that clears the blood of the obstructing uric acid is Nature's effort to burn up the microbes; and where capillary circulation is always free, as the result of a life in accordance with Nature, we know that the microbes are powerless.

The one thing that alters in these various conditions is the capillary circulation, and this can be easily seen and measured; the one thing that lies behind defective capillary circulation is excess of uric acid in the blood, leading by one or other process to the vicious circle previously mentioned.

This is just what we see in Nature, and gives a simple explanation of all the facts mentioned above, as well as of many more which could easily be mentioned, did space permit. Thus uric acid is the factor that controls the results of microbic invasion, and a life free from excess of uric acid is to a large extent a life immune from microbic injury; and this is so because uric acid controls the capillary circulation throughout the body from birth to death.

In conclusion I desire to express my gratitude to Dr. Gee for kindly allowing me to mention his experience, and to my son, Mr. K. G. Haig, for several interesting suggestions which have been made use of to illustrate the subject of this paper.

SOME OF THE OPEN QUESTIONS IN TUBERCULTSIS*

By THOMAS E. SATTERTHWAITE, M.D.,

NEW YORK.

To begin, with, some of us, but the laity more particularly, have been talking and writing about tuberculosis as if we physicians were just beginning to understand it. But Hippocrates, who flourished over thirteen hundred years ago, described it in unmistakable terms, laying down many specific rules for its management, including the use of cow's milk, outdoor exercise, and prolonged rest. Its contagious qualities also were mentioned by Galen, more than two thousand years ago, and he went so far as to say that phthisis was contracted by sleeping with a phthisical patient, living, eating or drinking with him, or even wearing his clothes. This doctrine prevailed until about the beginning of the nineteenth century. Indeed, as early as 1750, the disease was thought to be so contagious that in Italy public measures were adopted to check it. In fact, it is well known that on September 20, 1782, a royal edict was promulgated (in Naples), obliging physicians to report all cases of phthisis to the authorities; while in Rome, certainly as late as 1803, strict sanitary rules were adopted for controlling it. Even up to a date within the memory of living individuals, the consumptive was avoided by the Italians much as if he had the plague. Later, doubt began to be thrown on this doctrine, and it was gradually supplanted by that of a diathesis. Some of the French and English schools supported this view for a time, Sir Thomas Watson maintaining, in 1843, that, being a diathesis, it was not communicable from person to person. In 1857 the tide of opinion began to turn again, when von Buhl came forward with the contention that acute miliary tuberculosis was a specific infection. Villemin, in 1865, supported von Buhl's view by experiments on animals. In 1877 Piffard expressed the opinion (MEDICAL RECORD, July 21, 1877) that there was some infectious agent at the bottom of the trouble.

In 1881, the bacillus of tuberculosis was discovered by Koch, after the most elaborate series of experiments that had thus far been made. It is proper to stay, however, that miliary tubercles had been recognized by Mangetus, as early as 1700, while Laennec had been able to establish the unity of phthisis pulmonum with pulmonary tuberculosis. The special merit of Koch's work was that he separated the bacillus from the tubercle, developed a pure culture, and inoculated it so as to produce miliary tuberculosis secondarily.

At the present time, the bacilli that appear to be the most dangerous to mankind are the human and bovine, the bovine species having exceptionally active pathogenic properties, though how frequently the latter are factors in inducing human tuberculosis is still a somewhat uncertain matter. Birds, various animals, and even fish have tubercle bacilli, but they differ from the human variety in morphology, cultural characteristics, staining reactions, and pathological qualities. Each appears to be tenacious of these peculiarities, and yet under protracted cultivation, we are told, they seem gradually to approach each other morphologically. It is even possible that they may be bred so as to be somewhat akin to the human bacilli in virulent qualities. But thus far no satisfactory proof has been given that these non-human types are actual sources of tuberculosis. On the other hand, there is a so-called pseudobacillus, which has been obtained from feces, human sputum, and other sources, whose relationship to the bacillus of human tuberculosis has not been determined; it is said to differ from the genuine variety mainly in its quality of resisting decolorization by mineral acids, and for this reason is classed as an acid-fast bacillus. According to James, one, the Timothy grass bacillus, one of these pseudobacilli, produces reactions on inoculation akin to those produced by tuberculin. This statement suggests new opportunities for research workers.

In respect to the frequency of the disease, we have no very satisfactory data, and it is impossible to foretell when we may have them. We have only approximate estimates, and the reason is that we have to depend mainly on *postmortem* results, i.e., the ocular evidence yielded by lesions that have healed, and that may have been due to tuberculosis, or ordinary abscesses, syphilis, or even parasites, nothing pathognomonic remaining at the affected spot to show what may have been the cause.

For example, a few years ago (1900), Naegeli, of Zurich, reported from his *postmortems*, evidences of tuberculosis in 90 per cent; and pathologists as a rule are in agreement that there is a very high percentage in adult bodies. Burkhardt, of Dresden, in 1906, found about the same proportion as Naegeli, but Lubarsch put it as low as 70 per cent. Beitzke, of Berlin, however, who examined 1,100 bodies at the Charité, found a still lower percentage; he made it 58.2 per cent in persons over fifteen years of age. And yet he held that in certain large cities almost every adult body was tuberculous, a fact of pretty general acceptance at the present time.

The difference in the statistics of Beitzke and Naegeli depends chiefly on the fact that the former omitted from his classification the puckered scars of pleural adhesions at the apex, and the minute fibrous nodules, two to three millimeters in diameter, found in the lungs and pleura, while Naegeli and others held that these lesions represented healed tuberculous centers. If Beitzke had included these latter as evidences of old tuberculosis, then the figures of the two would be in closer agreement. What appears certain is that more than half of the adult population of the city of Berlin has had tuberculosis at some time or other, while it is tolerably certain that the actual ratio is very much higher. This statement brings out two definite facts: That most adults of advanced age have at some time or other had an attack of tuberculosis; and that in congested localities it is much more common than in the population outside of cities.

*Read before the Medical Association of the Greater City of New York, March 21, 1910.

As bearing on the former point, Von Pirquet has stated that almost everyone yields to his cutaneous tuberculin test.

Another interesting fact is that tuberculosis is very common among our negroes, though it is said to be unknown among the dark races of Africa. It is apt to run a rapidly fatal course in negroes; in fact, according to recent census returns, with them it is from two to four times as fatal as with white persons. Almost the same degree of frequency occurs with our Indians.

In respect to age, the following interesting facts as to fatality have been noted by Wallstein, of the Babies' Hospital, in this city, from her *postmortem* findings:

In the first year of life, 1.8 per cent of all deaths.

In the second year of life, 11 per cent of all deaths.

In the third year of life, first half, 16 per cent of all deaths.

In the third year of life, second half, 20 per cent of all deaths.

Other statistical returns from the same hospital, however, put the incidence in the first year at 5.6 per cent of all cases. Here we have a variance in statistics. But the 5.6 per cent represents the clinical plus the physical diagnosis, making, of course, the percentage greater. These figures may be used to support the theory that the disease was acquired by personal contact; indeed, in these instances it is said that of nearly one-half of the infantile cases of tuberculosis brought into this hospital in recent years the infants had been in close contact with tuberculous persons in their homes.

As a rule, tuberculosis does not occur with as great frequency in the early as in the later years of adult life. I have observed the same thing in cattle, especially among the high-bred. In fact it is clear that the incidence of the disease bears a somewhat constant ratio to the age. On the other hand, the period of the largest mortality of infants is during the first year of life; of adults in the third decade, or between 20 and 30.

The actual proof of contagion is not always easy. It is mostly derived from analogical reasoning. For while it is true that the lower animals can, as a rule, be successfully inoculated with the bacillary poison, the human species rarely takes the disease in this way from direct contact with tuberculous material. Butchers, pathological anatomists, general and special surgeons and dermatologists rarely take the disease by contact, though of course frequently exposed to it. And yet in most of these instances, the poison is wet, and therefore presumably in a form readily communicable. The theory of the dermatologists, who have to deal with the various forms of tuberculosis cutis, is that they are contracted through open wounds or an abraded skin. Epidemics are said to occur in this way among miners. So, too, skin tuberculosis is said to be comparatively frequent among the demented in our insane asylums, the theory being that with their uncleanly habits they contract the disease by contact. Of course, these skin eruptions may equally well be the local manifestations of a tuberculous diathesis. In respect to the contagious qualities of these forms of tuberculosis, dermatologists do not seem to evince much fear.

Thus far, it has been difficult to actually demonstrate that infection comes from the ingestion of contaminated milk or meat, though it has been inferred in some quarters that of all ingested matter milk is the greatest source of danger. Within the past two years, however, Professor Woodhead (MEDICAL RECORD, March 5, 1910), of the British Royal Tuburculosis Commission, has estimated that less than 7 per cent of all deaths from tuberculosis are due to bovine infection. In this connection, it has been urged by Whitla, of Dublin, that tuberculosis is rife in parts of the world where cows' milk is not used at all, while children are known to have utilized the milk of tuberculous cows for years without contracting the disease. Nor have we direct proof that the disease comes from sputum. Experiments on the lower animals, however, show that infection is possible from these two sources; from analogical reasoning, therefore, we are led to believe that the same methods prevail in the human subject. If we could supplement analogical reasoning with direct proof, the evidence would, of course, be more satisfactory.

Uncertainty on these points has led Baumgarten to state that there are three methods by which the disease can be transmitted: the aerogenous, where family and workshop epidemics result from air contagion through dust; the enterogenous, where the disease is the result of swallowing the bovine bacillus, which, however, he claims never produces a progressive tuberculosis, a view that is held by many; and the geneogenous, where the infection is due to the bacilli passing through from the mother to the fetus. This form of inborn tuberculosis will, he thinks, be more and more apparent with the improvement of our microscopic technique.

As already mentioned, the skin may possibly be the medium through which the bacillus enters, and numerous cases have been reported to sustain this view. Also, flies may carry and implant the germ. This latter method, however, is probably quite rare.

Inasmuch as the bacillus soon dies when exposed to light and air, it is not likely to be conveyed by dry sputum. But fresh tuberculous sputum contains the bacilli in vast quantities; hence the danger, which is intensified when the patient coughs in one's face. This, at least, is the theory of the contagionists, and yet the rapidity of infection seems to be intensified by the admixture of such organisms as the staphylococcus or other pus-producing bacteria, such as are to be found where there are suppurating pulmonary cavities, as in the last stages of tuberculous phthisis; on this point there is much unanimity of opinion. High elevations have few germs, hence in them the danger of contamination from dust is diminished. But what is most important in this connection is that the tubercle bacillus does not destroy tissue unless pus-producing organisms are affiliated with it. And so the bacillus alone is not as deadly as we thought it a while ago.

The query as to the ratio between those who inspire the poison and those who ingest it is put variously. As yet we have no material facts sufficient to use for decisive conclusions. The invasion by the air passages varies, according to the views of individual authors that I have consulted, from about 40 per cent to 69 per cent. On the other hand, invasion by the alimentary canal has been put at from 5 per cent to 35 per cent, while Koch has held that the disease is rarely or never contracted in this way, and his dictum necessarily carries with it the weight that attaches to the opinion of one of our ablest present-day etiologists. Taking the average returns of men who have in-

vestigated this point, it is about 21 per cent. Of course, such an average percentage has no precise value.

According to recent statistics (Vienna, in 1908), tuberculosis was prevailing in the proportion of 10 to 10,000 of the population in the better parts of the city, but in the poorer localities as 67 to 10,000. Where the families lived in one or two rooms, the mortality was double that where the family lived in four rooms and upward. However, these statistics do not necessarily sustain the doctrine of direct personal contagion; they are applicable also to deficient nutrition furnishing the base for ordinary aerial contagion, for the tubercle bacillus is very abundant in the air of all cities.

Whether chronic alcholism favors the development and extension of tuberculosis is a moot question. Alcoholism is a condition that is often found side by side with tuberculosis. The patient, feeling that his disease is taking away his strength, may resort to alcohol: in fact, he usually does. Undoubtedly, in many cases it is a food that prolongs his life. In other cases, however, it may increase malnutrition, and so hasten the end. Alcohol is a food for some, for others a poison.

The pure contagionists have thrown over the doctrine of heredity, or have considered its influence of minor account. This has been the trend of opinion of late. Some have held, however, that while persons do not inherit the disease, a physical condition of the chest may be transmitted that favors tuberculosis by inhibiting appropriate respiratory efforts. Others, and they are more numerous, hold that the contagion is inoperative without a certain soil in which the bacillus will grow. Some go further and say that a favoring soil is of as much importance as the germ; others say it is of more importance. That is, in plan language, according to this latter view contagion is not to be feared after exposure, if the individual does not offer a nidus in which it may develop. Others claim that there is in some a normal resistance that prevents infection, while a subnormal resistance invites the disease. Heredity has been claimed as a factor in as much as 60 per cent of infected cases. This, however, is certain: that a predisposition can be handed down; and the family history has its influence in the determination of the disease. Susceptibility or lack of resistance are also governing factors in the etiology of the disease.

One of the most noteworthy efforts toward the prevention of tuberculosis has been the barring of consumptive immigrants to this country by the Marine Hospital Service, while efforts to prevent the influx of those having consumption or suspicions of it have recently stirred the towns of Valhalla, New York; also Summit and Lakewood, New Jersey. Indeed, the residents of Lakewood, by a very large majority, have insisted that a proposed Preventorium should be moved away, and they have carried their point. In this last instance, however, there appears to have been no satisfactory evidence of personal danger, inasmuch as the proposed inmates of the institution were to be merely the children of tuberculous parents, incapable of communicating the disease, though capable of contracting it under unhygienic conditions.

At the present time, the general hospitals of this city are not allowed to take "open" tuberculosis patients, who are referred by the city authorities to the Metropolitan Hospital on Blackwell's Island, the Riverside Sanatorium on North Brother Island, St. Vincent's Sanatorium, St. Joseph's, or the Seton, of New York; if walking cases, to the various dispensaries. A limited number of "closed" cases are admitted to the general hospitals. The profession will look with great interest to see if these methods of combating the disease will prove satisfactory. In the opinion of the writer, open cases of tuberculosis pulmonum can with safety be admitted again to special wards in general or other hospitals, and the reopening of such wards will not only prolong life, and sometimes save it, but remove the very reasonable objection that under present methods consumptives are apt to be sent away to die far from their relatives or friends.

It is surprising how great an effort has been and is being made to check the disease in all civilized countries. During the past year alone, upward of $4,000,000 has been appropriated by 28 State Legislatures. Also, during the year 1909, 28 State or Territorial Legislatures passed laws pertaining to tuberculosis, and 64 laws relating to either the prevention or the treatment of consumption have been put on the statute books. New State sanatoria are to be built in seven states, while in six states existing sanatoria will be enlarged. Such institutions now exist in twenty-seven states. Also, according to a compilation under the Russell Sage Foundation, there are in this State thirty-three institutions that care for consumptives, charging from nothing at all up to $40 per week. Besides, ten states have in all nearly $100,000 to be spent in educating the public about tuberculosis. Traveling exhibitions are used in nine states and in Porto Rico. In addition, the last Congress appropriated $1,000,000 for the maintenance of three Federal sanatoria in New Mexico and Colorado. In all, it has been estimated that fully $8,000,000 will be expended for these purposes in this country during 1910.

Now for results. Optimists believe that we can eradicate the disease, and statistics can be used to support this contention. According to the English tables of Woodhead, of the Royal British Commission, there was a fall in the annual death rate in England and Wales, between 1867 and 1906, of nearly 52 per cent, so that if the same improvement were to continue for another forty years the disease would certainly disappear from those countries. Statistics must, of course, be accepted with caution; most of them contain increments of error. It has been calculated, however, by Menzies, that there is a recovery in 26 per cent of those infected. Whatever the ratio is to be ultimately can only be determined approximately, and then by the careful study of *postmortems*, by experts. For until we can differentiate, as I have already intimated, the *postmortem* findings in syphilis, traumatisms, inflammatory conditions (non-tubercular), including the results of parasitic infections, we cannot get very near the truth.

The returns of the Census should help us, however. According to it, from a national death rate in tuberculosis of 38 per 10,000, in the five years from 1838 to 1842, there was a fall to 12 per 10,000, in the five years from 1901 to 1905, both inclusive. The earlier census tables were quite capable of yielding very erroneous conclusions.

Also according to Bulletin No. 104, Bureau of the Census of 1909, Table 4, the death rate from all kinds of tuberculosis showed a decline to 173.9 per 100,000, in 1908, as against 183.6 for 1907, the average of the five years from 1901 to 1905 having

been 193.2. All this in the registration area. There was, however, a slight increase in the mortality rate in the registration states of California, Rhode Island, and Vermont. (Under the new census regulations and in the present registration areas we are gradually approaching to accuracy of figures). Still, inasmuch as the cost of the Tuberculosis Crusade, according to the National Association for the Study of Tuberculosis, was in 1908 $8,180,621.50, including $5,292,289.77 for the treatment of these patients in sanatoria and hospitals, the returns are naturally somewhat disappointing to optimists.

This is to be so mentioned that after all has been said and done, the brunt of the care of the tuberculous as a class, and including all cases, must come on the general practitioner. Whatever success may be attained will be largely under his direction and with his aid. And, in this connection, he must decry the methods of any municipality whose agents unduly examine, visit, and alarm the sufferer and those about him, prying into their household matters, so that in their distress they fly from one neighborhood to another, or even leave their homes to escape their persecutors. In a recent number of the Journal of the American Medical Association, it was stated that the City Council of Baltimore had inaugurated a system by which nurses were given authority to enter houses and enforce the city's regulations for preventing the spread of tuberculosis. It will result that a number of tuberculous paitents cannot be found, for obvious reasons, and then there will naturally be a demand for more of the public money to hunt them down. It is the very bad cases that are thus disturbed, more than the others; and yet it is these very ones that need absolute rest, physical and mental, and rest in bed. Procedures on the part of public authorities to alarm and needlessly distress these wretched sufferers should be discountenanced by us as practitioners.

When, too, tuberculosis is classed, as it has been, with such contagious diseases as smallpox and the exanthemata, great harm has been done. The following note is to be found in a circular issued by our Board of Health:

"In this provisional classification of the infectious diseases, arranged for practical purposes, the most readily communicable of these diseases, embracing the exanthemata and typhus fever, have been placed in a group by themselves and called contagious. This has been done with a view to emphasizing a distinction, which is not only of scientific significance, but of practical importance, in dealing with the sanitary features of administration. This distinction is furthermore of importance because it avoids the misunderstanding and alarm frequently caused by including in the same class the very readily communicable diseases (such as smallpox), and the much less communicable diseases (such as tuberculosis), which require very different sanitary measures for their control."

It is only to be regretted that the type of this note is small as compared with the text of the Code.

Instead of making the people at large phthisiophobiacs, the public authorities should also discountenance sensational announcements telling "How to Prevent and Cure Consumption." Such announcements are misleading, and may result eventually in a reaction against even sound methods. We cannot truly say that every case of consumption is curable. We can say, however, that all forms are curable under favoring circumstances. But there can never be a cure of consumption, in the sense that issue destroyed will be regenerated. Circulars issued by benevolent associations should be cautious, therefore, in what they hold out to the sufferers.

In a leaflet issued by the Charity Organization Society of this city, a page of advice ends with these excellent words: "Courage is very important; consumptives can be helped, and many are cured."

But our methods are capable of much improvement otherwise. Do we not see about us on all sides men in the first stage of the disease, who are quite able to work in the open air and would be much benefited by it, satisfied to be classed as chronic invalids; to visit the dispensary doctor, get their medicine free, and let a poor old infirm mother support them? I know of such a case at this moment. Or a patient may be discharged from a tuberculosis hospital because his sputum is negative, while his cough and temperature has disappeared. The open lesion has healed, but in the lungs there may be general tuberculosis of the fibroid variety, with dyspnea, tachycardia, and some debility. He cannot do the heavy manual work of his trade. Such a patient was sent to me lately by some philanthropic ladies. He had a wife and five children to support, but he was quite unable from feebleness to do his customary work, that of a stationary engineer. Notwithstanding, he was anxious for something to do, and was quite able to do various sorts of light work. No one, however, seemed able to find him this kind of work, and I was obliged to send him to a general hospital. In the present Tuberculosis Crusade we need employment bureaus to take over such patients; for them work would often be a far greater boon than hospital or dispensary treatment, and might even be more effectual therapeutically. Beds or medicine are not all of the treatment needed. There is an economic side to the tuberculosis question.

Unfortunately, a vast amount of money is being expended, I feel sure, without due regard for the proper method of combating the disease. Rapid results will naturally be expected from such enormous outlays, and if they are not soon forthcoming a reaction against the methods will follow. There are two important things to do: (1) Employ proper treatment while the disease is "closed" and incapable of causing infection, and (2) isolate and treat advanced "open" (or third stage) cases, so that they will not infect others. In this connection, however, we should realize that a certain number of open cases can be cured by the fresh-air method outside of hospitals. When cavities are small, they will often heal under favoring circumstances, such as healthy farm life, with good food and pleasant surroundings. Practitioners of general experience will support me in this statement.

In conclusion, it may be stated (1) with positiveness, that while tuberculosis is communicated by contact, it is not contagious to the same degree as many other diseases, notably the exanthemata, syphilis, and gonorrhea; moreover, it is only communicable under certain favorable circumstances. This fact deserves to be widely known. (2) That fully 50 per cent of all adults contract the disease at one time or another; in cities a much higher percentage. In fact, the tendency to the disease increases with age, in some sort of ratio, after in-

fancy, so that while it may exist in infants of two years in the low proportion of 5 per cent. at the age of ninety nearly everyone has had some experience of it. (3) The disease is contracted in various ways. What the ratio is between the different avenues of invasion has still to be determined. But it is a matter of the very first importance. (4) Many of the problems of tuberculosis are complex, and this fact should be impressed on the laity, who at the present moment are disposed to take a leading part in the crusade, without adequate knowledge of the problems involved. (6) There is also a humanitarian side to the question, apart from its scientific aspects. Public measures entailing unnecessary hardships for the individual or his family will necessarily retard the ultimate success of a movement, however good it is, and this is a philanthropic movement, that should enlist everyone's interest and support. (7) We have reached a point, also, where the intervention of the agencies of our National Government would be very helpful in the Crusade. For it is now an inter-state matter, like that of the water supply of our cities, and the pollution of our streams, all of which call for some sort of governmental control. The establishment of a National Bureau of Health would provide for the supervision of these matters, and physicians at large should sustain the hands of President Taft in endeavoring to establish such a bureau at the earliest possible moment.

SPECIAL DANGERS ASSOCIATED WITH OPERATIONS ON THE BILIARY PASSAGES AND THEIR AVOIDANCE.

By BENJAMIN T. TILTON, M.D.,

NEW YORK.

Operations for gallstones have become of late years so frequent and the indications and operative technique so firmly established that there seems little new to be added to the mass of literature on the subject. It is well though to remember from time to time that there are certain dangers associated with gallstone surgery which, however familiar to those with large experience, are of momentous importance in the prognosis, and if unknown to the inexperienced, lead to pitfalls and disappointing results. No branch of abdominal surgery requires more careful consideration of each case before operating and greater judgment in the operative work and after treatment. A failure to give due weight to the dangers and possible complications associated with this branch of surgery means high mortality, which may be quite independent of operative dexterity. A surgeon may perform a very skillful and rapid cholecystectomy and yet his patient may died because of lack of judgment in the selection of the operation or of disregard of the patient's power of resistance. The low mortality statistics of such experienced operators as Kocher, Körte, the Mayos, etc., depend much less upon a superior technique than upon an intimate knowledge of the pathology of gallstones, the manifold variety of the changes they produce, and particularly the dangers besetting their removal.

I desire here to call attention to the more important dangers connected with the surgery of gallstones and to emphasize the necessity and means of avoiding these dangers before, during, and after operation.

Diagnosis.—In the first place the diagnosis of gallstones is often attended with such difficulties that mistakes are easily made unless great care is taken. Not only are gallstones mistaken for other lesions, such as those of the stomach, appendix, kidney, etc., but the particular form of the disease fails to be recognized. It is most important, however, to know as accurately as possible the special conditions that one is to meet at the operation. To diagnose simple uncomplicated stones in the gallbladder and find on opening the abdomen a bladder distended with pus or an impacted stone in the common duct, may mean that the operator is unprepared to cope with the unexpected findings, and hence the success of the operation is jeopardized. This error in diagnosis can be somewhat compensated for if in every case the operator prepares himself for any form of pathological lesion of the gallbladder or bile ducts. At the same time an accurate diagnosis before operation lessens very much the dangers of the operative procedure and is possible in the majority of cases. For this purpose we should use every means at our command, especially an accurate history, careful and repeated local examinations, examinations of the blood, feces, etc. It is remarkable what accuracy can be reached by careful attention to the various methods of diagnosis at our command. Great weight should be given to the duration of the symptoms, the number of attacks, the character and location of the pain, and the existence of jaundice. In the physical examination particular attention must be given to points of tenderness, the existence of a mass, enlargement of the liver, pancreas, etc. It is important to remember that a very acute cholecystitis or an occlusion of the common duct may be the first evidence that the patient has gallstones, and hence the absence of typical gallstone attacks must not lead us to exclude the biliary passages.

Shock and Sepsis are dangers that attend many of the operations for complicated conditions in the biliary system, and their avoidance is not always possible. Much can be done, however, by careful judgment and it is here that experience is so valuable. In the first place, the proper choice of operative procedure is of great importance and may determine the outcome of the case. For example, the subjection of a septic, jaundiced, exhausted patient to a choledochotomy will often be fatal, whereas a temporary cholecystostomy for drainage, followed a few weeks later by removal of the obstructing stone from the common duct, will usually save his life and end in a complete cure. The removal of a septic gall-bladder which has ruptured and is surrounded by pus, means a very hazardous undertaking, whereas cholecystostomy by fulfilling the vital indication, viz., drainage, is the safer operation and may be supplemented later by a cholecystectomy, if necessary.

Shock and sepsis can both be materially lessened by selection in each individual case of the safest procedure, which in the urgent cases is the simplest and quickest one. The operator should not adhere to one method, but should select that one which is the most suitable to the case at hand. This may mean a secondary operation at a later date, but this is a wiser course to pursue than to attempt to do more than save the patient's life at the first operation. Even though the local conditions may be best served by a certain operation such as, for example, a cholecystectomy, we must not decide upon that operation if the general condition of the patient

does not warrant more than a cholecystostomy. The proper weighing of the local indications, the condition of the patient, and our own operative experience should precede our choice of operation in every case. In this way we shall avoid many of the catastrophies that come from a careless selection of operative method.

It is true that secondary operations on the biliary passages are often more difficult and, other things being equal, more dangerous than a primary one. For example, a cholecystectomy performed weeks or months after a cholecystostomy means the encountering of adhesions and a prolonged dissection may be necessary to expose the gall-bladder. The dangers from this source do not, however, in my mind, compare with those from performing a radical operation on a patient who is exhausted from prolonged fever, jaundice, and low diet, and whose kidneys and other organs are impaired. At the time of the secondary operation the patient has regained his normal strength and resistance and should be able to withstand, if necessary, a prolonged and difficult dissection.

Whatever operation is decided upon, it is important to remember that the operative manipulations must be simple and short, especially under certain conditions. A patient suffering from long continued sepsis, especially when combined with cholemia and enlarged liver, cannot withstand a prolonged operation, and hence the rule in these cases should be a small incision and the least amount of anesthetic and manipulation. In the presence of infectious foci, either inside or outside the biliary passages, the greatest care must be used to prevent sepsis by too much manipulation and opening up of fresh channels for absorption. Rapid provision for drainage should be the rule in these cases.

Hemorrhage following operations for gallstones need only be considered in its relation to cholemia. The latter condition, when marked, may mean very dangerous postoperative oozing, and many deaths occur from this cause alone. In case the obstructing stone in the common duct is movable, the jaundice may clear up from time to time, and during the interval operation is without serious danger from hemorrhage. In case of an impacted stone, however, the cholemia becomes more and more severe, the jaundice and its accompanying symptoms constant and more intense, and operation under these conditions is very hazardous. Delay now means increase in the operative risk, and one is often forced to take great chances in deciding upon operation. If it has gone so far that subcutaneous ecchymoses occur in different parts of the body, the hope of a successful result is practically nil. In its less extreme cases we may perform the comparatively slight operation of drainage of the gall-bladder and biliary system by means of a rapid cholecystostomy and wait for a more favorable time for removing the calculi from the common duct. In this way extensive manipulation is avoided and the amount of traumatism and hemorrhage reduced to the minimum.

If it is decided to attempt the removal of the obstructing calculus at the primary operation, certain prophylactic measures have been used to increase the coagulability of the blood and limit postoperative oozing. Among drugs the calcium salts have been extensively employed by many surgeons. On the whole their action has been disappointing. Kehr has used with some success the subcutaneous injection of gelatine. The preliminary injection of animal serum has had some advocates. Still better seems to me the employment of human serum. I have recently used the latter in a very bad case of cholemia due to common duct stone, in which the extreme jaundice with intense itching, slow pulse, anorexia, and emaciation had been almost constant for seven months. Encouraged by the remarkable results obtained by Dr. Welch in the treatment of hemophilia neonatorum in the Lying-In Hospital, I had three ounces of human serum injected the day before operation. There was practically no postoperative oozing, in spite of the fact that the viscera were markedly yellow. A very large stone was safely removed from the common duct and the patient made a perfect recovery. Direct blood transfusion has been recommended and is undoubtedly of service. If, however, the same result can be obtained by the very much simpler procedure of injection of serum, the very complicated transfusion operation would seem unjustified. If, in spite of these precautionary measures, dangerous oozing does occur after operation, it is advisable to repeat the injection of serum or resort to direct transfusion, both for restoring the blood lost and aiding coagulation. Infusion of saline seems to be of little avail in these cases.

Uremia.—Long continued inflammation of the biliary passages in the form of chonic cholecystitis and chronic cholangitis is followed gradually by inflammation of the kidneys of a subacute or chronic type. This fact must be borne in mind in operating upon these cases. To avoid serious disturbances of the renal activity we must examine carefully the function of the kidneys prior to the operation. A failure to do this may result in an unpleasant surprise when the patient suddenly develops anuria and uremia after the operation. It is not uncommon for middle-aged patients to be operated upon the day following admission to the hospital and succumb in 48 hours from arrest of renal function. This usually means the failure to discover prior to operation some form of nephritis. The importance of making such a discovery is, of course, great, as we can thus avoid the unfortunate and disheartening outcome of the case. To prevent this the operation may be postponed until the condition of the kidneys is sufficiently improved, or if the operation is urgent a proper selection of anesthetic and anesthetist can be made and the extent of the operative procedure curtailed.

Following the operation measures to stimulate the activity of the kidneys may be employed at once, particularly the Murphy irrigation, etc. These preoperative and postoperative measures should be carefully carried out if there is any evidence of nephritis in middle-aged subjects. Failure to do so will mean the loss now and then of a patient whose gallstone disease was perhaps of a nature that could have been borne with for many years under medical treatment. Such results bring discredit upon the surgery of cholelithiasis and it should be our aim to limit their occurrence by careful and repeated examinations of the urine before operation, so that we may be on our guard in case some renal lesion is found.

Pneumonia.—Like all operations in the upper half of the abdominal cavity, those upon the biliary passages are associated with the risk of postoperative pneumonia. This danger is more imminent in some classes of patients than in others. The aged, the alcoholic, and the plethoric are particu-

larly susceptible, and special pains should be taken with them to avoid this serious complication. In the first place the anesthetic is of great importance. If ether is given it should, where possible, be administered by one specially trained for this work, so that the patient receives the least amount possible and in a nonconcentrated form. Care should be taken while the patient is being washed, while under the operation, and while the dressings are being applied, not to expose too much the patient's body. After the patient is returned to his bed it is a good plan to raise the head of the bed several feet, so that the movements of the diaphragm may be as unrestricted as possible and thus allow the lungs free excursion. In the aged it is well to sit them up in bed very promptly the second day, so as to avoid hypostasis. It is wise to get such patients out of bed at the earliest feasible time.

In thus enumerating the more important dangers connected with gallstone surgery and pointing out the means of avoiding them, I have tried to make the experience gained from my work and that of colleagues of assistance to those beginning their operative experience in this field. I feel confident that careful attention to these warnings will be helpful in preventing the operative disasters which may happen to the experienced, but which are of frequent occurence to those ignorant of the special dangers of gallstone surgery.

121 East Thirty-eighth Street.

THE USE OF DAY CAMPS AND NIGHT CAMPS IN THE HOME TREATMENT OF TUBERCULOSIS IN NEW YORK CITY.*

By N. GILBERT SEYMOUR, A.B., M.D.,

NEW YORK.

ATTENDING PHYSICIAN GOUVERNEUR HOSPITAL TUBERCULOSIS CLINIC. ASSOCIATE DIRECTOR ST. GEORGE'S TUBERCULOSIS CLASS.

The day camp is a comparatively recent factor in the home treatment of tuberculosis in New York City. The night camp was its logical sequel. The separate clinic, devoted exclusively to the treatment of tuberculosis, was inaugurated in New York sixteen years ago, but the establishment of such clinics did not become general among the city dispensaries for ten years afterwards, and the day camp was not a factor in the tuberculosis crusade until the summer of 1907, when the Relief Committee of the Charity Organization Society, the forerunner of the Association of Tuberculosis Clinics, first utilized an old ferryboat for this purpose. The *Southfield*, condemned for active service, was secured from the city, equipped with the mere essentials for such use, and maintained as a floating day camp, tied up to a wharf at the foot of West Sixteenth street, for the summer months.

This venture proved so successful that the *Southfield* was secured the following year by the Bellevue Clinic, stationed at a wharf in front of Bellevue Hospital, and has been in commission there, summer and winter, ever since. The liberal use of white enamel paint, and the addition of running water, shower baths, sanitary plumbing, and steam heat, have transformed the old hulk into a veritable floating hospital, admirably adapted to the purpose it now serves.

This transformation of a condemned municipal ferryboat—unfit for active service and consigned to rot away at Staten Island, a useless and unsightly mass of old timber and rusting machinery—into an open air camp for the treatment of tuberculosis was an idea speedily imitated by two more of the city clinics, the Gouverneur and Presbyterian Hospital Clinics. During the summer of 1908, two other old ferryboats, the *Westfield* and the *Middletown*, were rescued from the junk heap, with the consent and assistance of the city authorities, and were towed up from Staten Island to their present quarters on the East River, at the foot of Jackson street and of Ninety-first street respectively, where they were made fit for their present service.

The Presbyterian boat camp was made possible through the generosity of Mrs. J. Borden Harriman, chairman of the Women's Auxiliary of the Presbyterian Tuberculosis Clinic, who sustained the expense of its renovation and equipment. It is by far the most elaborate and ornamental of the remodeled ferryboats, and boasts an average daily attendance of seventy-nine. Within the past year, the Presbyterian Clinic has relinquished the control of this camp, which is now maintained by the Board of Health.

The Bellevue boat has also been made more ornamental, as well as more suitable for its purpose, at a considerable expenditure of money. It is now equipped with every necessity for use both day and night, at all seasons of the year.

The Gouverneur boat alone has been altered only so far as to make it habitable, and with the least possible expenditure. With its exterior unpainted and its rusty smokestack, the old *Westfield*, as one approaches it from the wharf, looks the picture of forlorn and useless delapidation; but the interior—with its model kitchen, its immaculate dormitory and dining-rooms, its open air school room, and its general air of service with efficiency—makes an altogether different impression.

I speak of the Gouverneur boat with more assurance, and with no intention of drawing a comparison, because I have been associated with the Gouverneur Tuberculosis Clinic since its organization, six and a half years ago, and the camp is one of the by-products of its activity in the Gouverneur district.

The ferryboat *Westfield* and the use of Pier 53, East River, at which it is moored, were secured from the city authorities through the initiative and energy of Mrs. Edward Mandel, the chairman of the Women's Auxiliary to Gouverneur Clinic. It was opened July 11, 1908, and was conducted until October 25, practically as a private enterprise, and the figures of that early venture will serve as an illustration of how much can be accomplished with limited funds, provided enough enthusiasm and executive ability can be brought to bear on the problem.

During that first season of 1908, the *Westfield* was used as an open air camp for consumptives for seventy-one consecutive days. In this time ninety-nine patients received the benefit of the treatment, the average daily attendance being twenty-five. During this period, also, the first attempt at a night camp was initiated, nine of the men patients, for whom cots and bedding were provided, being allowed to sleep on the boat. On the closing of the camp in October, necessitated by inadequate facilities for winter weather as well as by the exhaustion of available funds, forty-five patients had im-

*Read before the Public Conference on the Prevention and Cure of Tuberculosis at Montclair, N. J., April 25, 1910.

proved sufficiently to be able to return to work, and it was possible to send nine others to sanatoria. The remainder continued their regular treatment at the dispensary.

The cost of the undertaking was as follows:

Initial expense of putting boat in condition	$194.53
Nurse—Furnished and paid by the Health Department	175.00
Services, including assistant nurse	240.15
Food and medical supplies	219.96
Car fare and loans to patients	33.80
Office, printing, postage, and telephone	28.65
Sundries, including laundry	7.86
Average cost per patient per day	.40½

This, it must be admitted, is reducing the operation of a day camp to its simplest terms. It will be seen that, with the exception of the salary of the head nurse, which was generously assumed by the Health Department, the entire amount was raised and administered by the Women's Auxiliary. It was a large undertaking, splendidly carried through, but the limitation of funds made necessary certain limitations in the work. It was not possible, for example, to provide an adequate noon meal for the patients, and the amount of milk and eggs supplied was necessarily limited. The point was proved, however, that a day camp could be conducted in connection with a large city clinic without an expense out of proportion to the benefit derived from it; and having established that fact, for which she had long contended, Mrs. Mandel gladly relinquished the management of the boat to the city authorities.

The *Westfield* is now under the official management of the Trustees of Bellevue and Allied Hospitals, and with the consequent increase of funds, equipment, and facilities we are now able to report these additional figures for the work of the last year (1909):

From May 19, 1909, to January 1, 1910—that is, from the opening of the camp under municipal control up to the beginning of the present year, a period of seven and a half months—331 patients were admitted: 187 men, 81 women, 27 boys, and 36 girls. During this time there have been discharged from the camp 238 patients: 156 men, 49 women, 17 boys, and 16 girls. There were, therefore, under observation at the camp at the beginning of this year 93 patients: 31 men, 32 women, and 30 children. At the time of their discharge 30 patients were improved and 9 were arrested, 24 were able to return to work, 49 were sent to sanatoria, 5 returned to Europe, 7 were sent to the country, and there were 3 who died. The total attendance of all patients, at both day and night camps, during this time was 14,941. The average daily attendance was 62. A more detailed account of the medical aspect of the work is not within the scope of this paper. As to the cost, I am unable, at present, to give the figures, since our supplies of all kinds are now furnished, on requisition, from Bellevue and Allied Hospitals.

We have now three salaried nurses on the boat—two by day and one at night—as well as a teacher for the school, a clerk, a night orderly, a cook and a scrub woman. The upper deck has been fully equipped for a night camp, with accommodations for thirty men patients. An open air school for tuberculous children is conducted daily, our teacher being provided by the Board of Education. A hot noon meal is served to all patients, and additional milk and eggs are provided in the morning and afternoon. It is possible now to accommodate not only our own suitable cases, from Gouverneur Clinic, but also those from the two tuberculosis districts adjoining ours, that of the Good Samaritan and the New York Dispensary Clinics.

The routine management of the city camps is similar in all essential particulars. I shall describe that at the Gouverneur camp only because I am more familiar with it. The patients attending day camp are required to report at 9 o'clock in the morning, when their temperature and pulse are taken and recorded by the nurse. Those who have been selected by the physicians as suitable for light work are detailed, in rotation, to do some of the necessary work of the boat. The heavier cleaning and the cooking are done by paid assistants. The majority of the patients are required to rest quietly in their steamer chairs in the open air—the women on the upper, the men on the lower deck—the greater part of the day. Here they may read, or write, or sew, or chat, except during the dinner hour, the serving of morning and afternooon nourishments, and during the "rest hour." Between 1 and 2 o'clock in the afternoon, directly after dinner, absolute silence and rest is enforced, the patients being required to stay quietly in their chairs, all work and conversation forbidden. Many of the smaller children, and some of the older patients, sleep through the rest hour, a habit which we encourage.

The children have regular school hours, somewhat shorter than the ordinary, and are also given selected breathing exercises and calisthenics under the supervision of the physicians. Their school room is the open air.

Strict sanitary rules are enforced with all patients, the penalty of carelessness or disobedience being dismissal from the boat. These rules are displayed on conspicuous placards, printed in English and Yiddish, the latter being our prevailing tongue in the Gouverneur district, and they are also given, on small printed leaflets, to each patient admitted to the camp. All patients are required to be familiar with them.

The day patients are dismissed at 5 o'clock, after the afternoon temperature and pulse are recorded. They are weighed, and the weights charted, once a week. We are now making an effort to adapt the dietary to a standard of caloric efficiency, but this is rendered difficult on our boat by the racial prejudices of our patients, the overwhelming majority of whom are Hebrews, to whom some foods of high caloric value, as bacon, are not acceptable. On the Gouverneur boat only Kosher food is served, since the introduction of which practice our attendance has notably increased.

The physicians associated with the work of Gouverneur Clinic visit the boat regularly, for medical rounds, as well as seeing all Gouverneur cases every week at the dispensary.

Many of our night camp patients also attend the day camp, thus living on the boat, under much the same discipline that they would follow at a sanatorium. Several of them are able to work by day. Night camp patients are required to report to the night nurse not later than 9 o'clock. Their morning and evening temperatures are recorded, and they are weighed every week, just as the day patients. They sleep on comfortable and sanitary hospital cots, with clean, fresh bedding—for the

care of which they are held responsible—and, though protected from wind and rain, they sleep in the open air. The contrast between the night camp dormitory and the average tenement home, especially on a stifling summer night, is startling; and yet some of the more ignorant of our patients can with difficulty be persuaded to remain. Such is the work of the Gouverneur day and night camps, and the results, the improvement in the condition of the patients—as recorded in symptoms, physical signs, and gains in weight—more than justify the expenditure of time, effort, and money.

Before concluding this account of the larger city day camps, mention should be made of the splendid day and night camps maintained by the Vanderbilt Tuberculosis Clinic, on the roof of the Clinic building, and by the Tuberculosis Clinic of the Nose, Throat, and Lung Hospital. I am not personally familiar with the details of the work of either, but they are both completely equipped and excellently conducted.

The abandoned ferryboat, with its ample deck room and open cabins, and with its location and outlook, on all the endless variety of river and harbor activities—provides an almost ideal camp for New York clinics; but the expense of adapting such a boat to such a purpose is considerable, at the very least, and can only be justified by the large numbers of patients who can be treated. Obviously, such boat camps are only feasible in large cities with long water fronts and abundant wharfage.

Even in New York, the boat camp cannot wholly, or even very largely, solve our problem. There are a very limited number of such boats, of places to put them, or of clinics to support them. Furthermore, in dealing with smaller and selected groups of patients, as in the tuberculosis classes, the problem of a day camp is a very different one. Such patients cannot, or will not, attend a large city boat camp, and it is often well-nigh impossible, in New York, to secure them outdoor treatment at their homes. It is forbidden by law to use the fire escapes for this purpose—although, in the case of a tuberculous patient, an infringement of the law is sometimes overlooked—and the landlords and neighbors of our patients seem to have a rooted objection to such use of tenement roofs. Dr. Pratt in Boston speaks of the use of back yards as suitable for tents and shacks. Back yards large enough to serve this purpose are beautifully lacking in most of our New York tenements, and, when present, are preempted by everything from stray cats to the week's wash. It is often only by moving an entire family into light and sunny quarters, and providing a window tent for the patient, that we have been able to solve the problem for some of our class patients at St. George's.

That was our predicament before the establishment of our own day and night camp on the roof of St. George's Deaconess' House. This was made possible, in February, 1909, through the generous coöperation of the Deaconess House Committee, and has been one of the most successful features of our work during the past year. The top floor of the Deaconess House, which communicates with this roof, was originally planned as a miniature hospital floor for convalescent patients. As our tuberculosis class work grew, it was felt that a greater amount of good could be done for a greater number of persons by placing this floor, and its equipment, at the disposal of the class. Our camp therefore consists, in addition to the roof, of a bedroom (used as a dressing room only, since no patients are allowed to sleep indoors), a bath room, private hall, dining room, and diet kitchen. The hall communicates directly with the flat, brick-tiled roof, partly covered by glass and open to the south. The bright colored awnings and window boxes gay with flowers make a cheerful picture on sunny spring days; but, summer or winter, rain or shine, our patients are required to be out.

The routine of the camp is, on its smaller scale, not unlike that already outlined, except that the patients take and record their own temperatures, and are weighed at class every week. The parish nurses and the senior deaconess supervise the daily management of the camp, and members of the committee and one of the class physicians visit regularly. A hot noon meal is sent up from the house kitchen, but separate dishes and utensils are used at the camp and are sterilized by boiling. Milk and eggs are provided morning and afternoon, as well as supper and breakfast for the patients living, night and day, upon the roof. Those attending night camp only receive their breakfast, getting supper at their homes after their day's work.

As the roof space is limited, not more than twelve patients by day and five at night can be accommodated, and only women and children are thus provided for at present. We hope soon to be able to open a similar camp for men on the roof of St. George's Trade School building. At present we have three patients living at the camp day and night—one of whom is kept in bed the entire time, except the afternoon she attends class. One patient comes at night only, a graduate who is now at work. Five others are attending only in the day and go home to sleep.

The average running expenses of the camp amount to about $18 a week, that is, about 28 cents per patient per day.

Since we have been able to conduct this day and night camp at St. George's, we have adopted a new method of discharge for our class members. Heretofore, candidates for discharge—cases arrested or apparently cured—were merely graduated from active membership and allowed to return to work, being required to report every month, at first, for observation; and, later, less frequently, if no relapse occurred. Now, our recent "graduates" are required to attend night camp at first upon returning to work—thus getting ten to twelve hours' treatment, at rest out of doors, in the twenty-four—until we deem it safe to restore them wholly to the home environment. It is on this same principle, of making the transition from active treatment to everyday life less abrupt, that we now readmit to the class, after their discharge from sanatoria, those patients whom we have been able to send away.

In conclusion, it seems to me that the day and night camps, as I have seen them in operation, play, in at least three definite ways, a very important part in this crusade against tuberculosis—whether they are conducted in connection with a large clinic, on a large scale, like our ferry-boat camps, or in connection with a church class, on a small scale, like our roof camp at St. George's. First:—They provide the essential of treatment—rest in the open air—under supervision and in a favorable environment. Second:—They provide a place where sanatorium discipline and régime can be taught and maintained. Third:—They provide a place where patients well enough to work by day, or upon their

return from sanatoria to home environment, can continue to take the treatment twelve hours out of the twenty-four.

I know of no means at our command which supply these important features of our work better than the day and night camps.

129 East Seventeenth Street.

A SIMPLIFIED METHOD FOR THE TRANSFUSION OF BLOOD.

By ARCHIBALD M. FAUNTLEROY, M.D.,

passed assistant surgeon, united states navy.

The well-known value of the transfusion of blood for such conditions as great loss of blood resulting in profound shock, hemophilia, and anemic conditions is familiar to all modern surgeons through the published efforts of Crile, Brewer, and others. The great drawback to its more general use as an effective surgical therapeutic procedure is not only the skill necessary in carrying out the prescribed technique, but the methods as previously described have been regarded by the profession at large as too complicated for general use outside the well-equipped hospital. In the hands of experienced surgeons who have used these methods the results have been most encouraging, but to be effective the operation must be performed by one expert in the use of the various tubes as heretofore recommended.

To be regarded as of practical use by the general surgeon in his every-day work there are several factors which would seem to be indispensable for its favorable reception. First of all, a more simplified technique; secondly, an apparatus which can be extemporized if necessary and requires no special skill to use; thirdly, a shorter time in performing the operation and a less formidable surgical procedure. Any method that will meet these requirements efficiently in actual practice would undoubtedly fill a long-felt want and is the writer's excuse for presenting the following method which he has used with great satisfaction several times on cases which will be reported later.

This method consists in a vein-to-vein anastomosis by means of a curved glass tube, one-eighth inch inner diameter and three inches in a straight line from tip to tip. Each end of the tube is slightly flanged to prevent slipping out of vein after ligature is tied. The veins at the elbow are the ones selected for use in both donor and recipient and, depending on the position occupied by the individuals, a full curved or an S-shaped tube is used, the former being known as the "hand-to-shoulder" tube

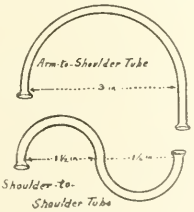

Fig. 1.—Tubes for transfusion; one-third the natural size.

and the latter as the "shoulder-to-shoulder" tube. In other words, when the transfusion is done with the donor and the recipient lying in the same direction, with their shoulders touching, or nearly so, the S-shaped or "shoulder-to-shoulder" tube is used, as the direction of the venous current in this position is the same in each individual. If for any reason the reverse position is selected, such as where the head of the donor is near the lower extremity of the recipient and where the hands of each are near the other's shoulder, the U-shaped or "hand-to-shoulder" tube is used as, in order to effect an

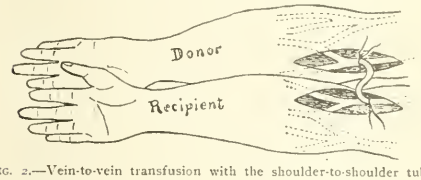

Fig. 2.—Vein-to-vein transfusion with the shoulder-to-shoulder tube.

anastomosis, the venous current from the donor has to be switched around into the venous current of the recipient which is running in the opposite direction. In making this tube, which is curved to represent the arc of a circle three inches in diameter, one arm extends below the semi-circle three-quarters of an inch, and it is this end of the tube which is inserted into the recipient's vein.

The actual technique is as follows: The tubes are prepared first by being boiled and then dropped into melted paraffin, from which, after a few seconds, they are removed with sterile forceps and shaken out to get rid of the excess paraffin and then laid aside in sterile gauze to cool. The outer paraffin is afterwards wiped off when cooled. The arms of both donor and recipient being thoroughly asepticized for six inches above and below each elbow, and sterile towels being arranged to prevent contamination from unclean parts, a rubber tourniquet is placed around the upper arm of the recipient to make the veins prominent and a three-inch incision is made over the median cephalic, or median basilic, through the skin, superficial fascia and fat. The vein at once comes up into the wound and a few strokes of the knife will liberate it completely from surrounding parts for an inch and a half or more. Two ligatures are now passed under the liberated vein, one in the upper and one in the lower angle of the wound, the lower ligature being tied and the tourniquet removed.

This completes the first step in the operation and the operator immediately turns his attention to the donor. The rubber tourniquet is adjusted and the vein exposed and liberated in the same manner as the recipient's vein. The ligatures are placed in the same manner, but in this case the upper one is tied and, while the vein below is being gently held by rubber protected forceps, it is divided completely just below the upper ligature. The operator now grasps the intima of the divided vein with fine pointed forceps and the assistant, being in readiness with the tube, inserts one end into the vein for about a quarter of an inch. The lower ligature is now tied, securing one end of the tube in the donor's vein.

The elbows of the patients are now approximated and the operator picks up with thumb forceps a small portion of the recipient's vein and makes a valve-like opening with a pair of scissors in the same manner as for salt infusion. The donor's vein is now released by removing the rubber protected forceps and the blood allowed to flow through the tube, which is then immediately inserted into the slit in the recipient's vein and secured in place by means of the upper ligature, which has been left untied for this purpose. The tourniquet on the

donor's arm is kept in place throughout the operation and is adjusted sufficiently tight to secure a well-marked venous hyperemia in the forearm and a consequent increased venous pressure. This pressure is ample to force the blood into the recipient's vein, but care should be taken that the tourniquet does not obliterate the radial pulse.

In the writer's cases the anatomosis was kept up for thirty minutes and then the tubes were removed, veins tied, and wounds sutured and dressed. Of course, the donor's pulse and general condition is closely watched, while hemoglobin estimations may be made from time to time from the finger blood of the recipient. When the tube has been secured in both veins it must be watched to see that angulation of the veins does not occur from movement on the part of the patients. If this is not guarded against the blood in the tube will clot and necessitate removal. Ordinarily the progressive improvement in the recipient's pulse, as well as his color, the latter shown by his lips, cheeks and ears, together with noting the fullness and tension in the recipient's vein close to the tube, is sufficient evidence that blood is passing from one to the other. Additional information is, of course, obtained by the hemoglobin estimations and by a blood pressure apparatus on the recipient's free arm. These latter steps are not considered essential, although if the appliances are at hand they may be used.

In addition to the tubes described there are two straight tubes about five inches long, properly flanged at each end and having the same internal diameter as the curved tubes. These straight tubes, after heating over an alcohol lamp, may be curved into any desirable shape in case other veins than the ones at the elbow are selected or in case of some anatomical abnormality on the part of either person. A full set of these tubes cannot only be readily obtained at very short notice in a city of any size from the instrument-makers or glass blowers, but any one, with a little practice, can easily turn out for himself a set that will answer every purpose. The small flange at both ends of the tube is easily made by heating the end of the tube and gently pressing a sharp-pointed piece of metal into the bore of the tube. An ordinary sharp-pointed wire nail answers the purpose nicely. The thin glass tubes may be obtained in any quantity and length from the manufacturers. It has been suggested by others who have used these tubes that it would be well to have three different sizes of each style tube made, so as to fit large, small or medium size veins, as conditions may arise. This may be a practical point to bear in mind, although the writer has never experienced any difficulty in using the size tube as given above.

The writer does not claim originality in the vein-to-vein method, but he does claim that the use of the curved tubes as indicated will greatly facilitate the use of this method in the hands of the general surgeon. The technique with these tubes is simplicity itself and any one who can perform the simple operation for the infusion of salt solution can perform this operation with equal ease and satisfaction.

Note: In the *Journal of the American Medical Association* for August, 13, 1910, in an article on vein-to-vein transfusion of blood, Dorrance and Ginsburg bring out the advantages of this method, the indications, and contraindications. In brief, their animal experimentation, besides operations on the human subject, would seem to indicate a decided advantage in favor of the vein-to-vein over the artery-to-vein method of transfusion.

THE JUVENILE FORM OF GENERAL PARESIS, WITH REPORT OF A CASE.

By JAMES V. MAY, M.D.,

BINGHAMTON, N. Y.,

ASSISTANT PHYSICIAN, BINGHAMTON STATE HOSPITAL.

The relation between syphilis and the parasyphilitic diseases has long been a subject of controversy and has furnished the basis of many important researches during the past few years. The discovery of the Wassermann reaction at first gave great promise of definitely disposing of this much debated question. It was soon found, however, that diseases other than syphilis gave the Wassermann reaction, and, a fact of much greater importance, that the reaction depended on the action of lecithin and possibly other substances having antigenic power, and not necessarily on the actual presence of the virus or organism of syphilis. The *Treponema pallidum* capable of almost universal demonstration in primary and secondary syphilis has not as yet been found in tabes and other parasyphilitic diseases. It is generally believed that general paresis can only result from syphilitic infection, although this is not as yet susceptible of absolute proof. The disease in adults in the great majority of cases gives a defi-

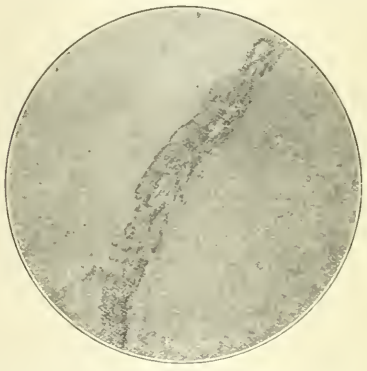

Fig. 1.—Cortex, second right frontal region, showing infiltration of the meninges (low magnification.)

nite history of syphilis. The etiological factor, although undoubtedly the same, is much more difficult to trace in cases coming on in childhood as a result of hereditary syphilis or infection acquired at an early age. The type of the disease, moreover, in juvenile cases presents some different features clinically and is well worthy of further study.

The onset is characterized by a gradual change in the disposition of the child, with an arrest of development, both physical and mental, often attributed to some accident or other traumatism, failure of memory, apathy, and indifference, with possibly a brief mental depression or a short manic attack and occasional hallucinations and delusions, followed by a progressive mental deterioration, with or without epileptiform convulsions, and terminating finally in complete imbecility. Physically there are tremors in the lips, tongue, and facial muscles, with a resulting speech defect, the pupils are unequal, irregular, and sluggish or completely immobile; there is a muscular incoordination, a marked increase or absence of the deep reflexes, changes in the gait, usually with ataxia, muscular weakness or actual paralysis, and contractures with

trophic disturbances, death occurring from exhaustion, bronchopneumonia, or some intercurrent infection. The nature of the disease is often overlooked on account of its infrequency in childhood and the absence of any definite syphilitic history in some cases. The children are often normal men-

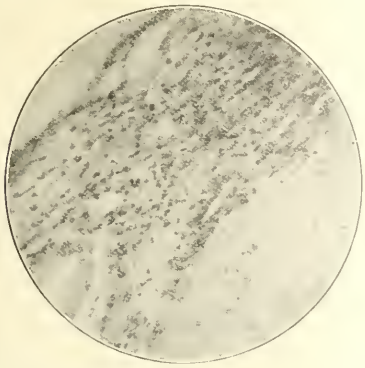

Fig. 2.—Cortex, second right frontal region, showing infiltration of the meninges (high magnification).

tally previous to the onset of the disease, and sometimes unusually bright. A history of some head injury may be misleading. Progressive mental deterioration may be due to various causes. The expansive type of the disease so common in adults is infrequent in children and the paralysis and convulsions are sometimes attributed to other causes. The duration is longer than in adult life. The frequency of infantile forms of paralysis, followed by imbecility and sometimes by epilepsy, adds to the difficulty of the diagnosis. The disease may be confused with cerebral syphilis, brain tumors, and the hereditary forms of ataxia (Friedreich) or spastic paraplegia, seven cases of which were recently reported by Punton[1] as occurring in two families. An absolute diagnosis can be made only by a microscopic examination of the nervous system, post mortem, as a lymphocytosis may not always occur in the spinal fluid and, when present, may be due to other causes. A positive Wassermann reaction is of course of great value but does not exclude other disorders of a syphilitic origin. The pathology of the disease is not essentially different from that in adults, except that degenerations in the cord may perhaps be more frequent.

Fairbanks of Boston[2] has summarized 38 published cases in which the onset occurred before the fifteenth year. The diagnosis was confirmed by autopsy in 29 cases. The average duration was four years. Nineteen were normal mentally previous to the onset of the disease, 8 were unusually bright and 9 were dull. In 19 of the cases there was a history of general paresis or syphilis in the parents, or a history of syphilis in either brothers or sisters. In eight others one or both parents showed syphilitic stigmata without a definite history of the disease. Five had parents who were insane. In 4 of the 38 cases no history was obtainable and in only three cases was it absolutely negative.

A case which is interesting on account of its duration, hospital residence, and confusing symptomatology has recently come to autopsy at this institution, and would seem well worthy of study. I am indebted to Dr. John Irvine McKelway for the family and personal history, as well as the clinical records of the case, which was under his care for some time.

The patient H. V., white, male, was admitted to the hospital on March 2, 1908, at the age of 16 years and four months. His family history shows several points of interest. His maternal great-aunt died insane and his maternal aunt suffered from epilepsy. His father is a man in good physical health as far as could be determined, and apparently normal mentally. The patient is the illegitimate child of a tuberculous woman 36 years of age. She has had two miscarriages since and has had four healthy children by another father. There is no definite information as to the existence of syphilis in either of the parents. The patient was a normal child and attended school until he was 13 years old, commencing at the age of seven. He was considered as being unusually bright and was very quick to learn. When 14 he went to work on a farm, but was mistreated by his employer, who is said to have kicked him in the abdomen and afterwards struck him on the head with a trace from a heavy set of harness. The patient returned to his home complaining of abdominal pain and showing numerous bruises. His illness dated from this time and was attributed to the assault by his parents. It was soon noticed that he was duller mentally and his speech indistinct. His gait became unsteady and peculiar athetoid movements of the fingers were noted. These symptoms gradually grew worse until his gait became decidedly ataxic, his speech hesitating and slurring and he had almost constant purposeless movements of the hands and arms. At this time he was irritable and fault-finding, somewhat dull, with apparent hallucinations of hearing and vision, and was very untidy in his habits.

On admission his appearance was that of a moderately well nourished and fairly well developed boy of 16, weighing 100 pounds, and measuring 62¾ inches in height. The roof of the mouth was narrow, with a high arch, the lobules of the ears were adherent, and typical Hutchinson teeth were evident. His gait was ataxic and he found it difficult to stand or walk without assistance. There was a marked tremor of the tongue and facial muscles.

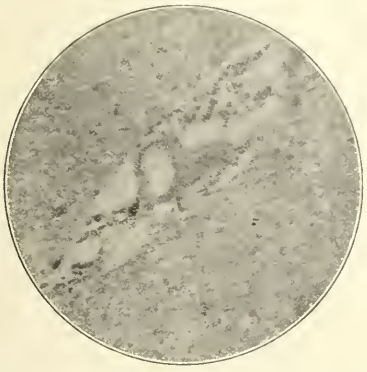

Fig. 3.—Cortex, second right frontal region, showing perivascular infiltration.

The deep reflexes were diminished. The right pupil was dilated and did not react to light, while the left was contracted and reacted slightly. Mentally he was dull and apathetic and answered all questions with the one word "Yes." The patient's general physical strength gradually declined. His weak-

ness and inability to stand or walk necessitated his remaining in bed after he had been in the hospital for about nine months. At this time he showed considerable emaciation, with rigidity and atrophy of the muscles of the legs and some apparent anesthesia of the lower extremities. Owing to his mental condition nothing definite could be learned in regard to either pain or temperature sense. There was a Babinski reflex on the right side, with a slight ankle clonus on the left. The patellar reflexes were absent. The patient was very awkward in the use of his hands, being hardly able to feed himself. The grip was markedly weakened on both sides. Muscular rigidity and contracture of the lower limbs followed in a short time. There were tremors of the hands with athetosis of the fingers and frequent irregular movements of the head. There was no pupillary response on the right side, with only a slight reaction on the left. There were numerous spots of old choroiditis in both eyes, with normal vessels. The optic papilla was normal on the right side, but could not be seen on the left on account of lack of cooperation. The patient, who for months had been able to say only "God damn, shut up," and "No," soon became entirely unable to speak. A mitral systolic murmur was heard at times. An examination of the blood showed practically a normal count, with nothing of interest otherwise. Uranalysis showed neither albumin nor casts. A lumbar puncture showed no lymphocytosis in the spinal fluid. It is possible that subsequent examinations would have revealed its presence had they been possible. After a gradual and uneventful decline, and a bronchitis of some duration, death resulted from a brief attack of bronchopneumonia, after a hospital residence of practically sixteen months. The complexity of symptoms left room for some discussion as to a diagnosis. The paraplegia with ataxia of both upper and lower limbs, the choreiform movements of the arms and athetoid movements of the fingers, the irregular movements of the head, the absence of convulsions, the impediment of speech, the Babinski reflex and ankle clonus, with Romberg's sign, pointing to an involvement of both the posterior and lateral tracts of the cord, and in the absence of any lymphocytosis in the spinal fluid, suggested the possibility of Friedreich's ataxia. The history of the case with the nature of the onset of the disease, the prominent speech impairment, the absence of any evidence of a localized meningitis or gumma formation, the absence of any involvement of the cranial nerves, the permanent nature of the paralysis and the profound character of the mental disturbance all militated against a diagnosis of cerebrospinal syphilis. The absence of nystagmus, the presence of tremors of the lips, facial muscles, and tongue, the pupillary changes, which are unusual in Friedreich's ataxia, and the marked mental deterioration particularly, terminating in complete imbecility, the characteristic speech defect and the syphilitic stigmata finally led to a diagnosis of the juvenile form of general paresis, with an involvement of the lateral and posterior tracts of the cord. While the tabetic form of general paresis is not rare in adults, the pronounced evidences of a combined involvement of various cord tracts gave rise to some question in regard to the diagnosis at first.

An autopsy was performed three hours after death. The body was much emaciated and weighed only 53.3 pounds. The musculature was generally atrophic. The left leg was flexed on the thigh and the thigh on the abdomen as a result of contractures. There was a small bed-sore over the left hip. The brain was quite small in size and weighed 1020 grams. The dura was slightly thickened, but not adherent. The pia showed a slight congestion throughout, with some opacity over the convexity. There was a slight excess of cerebrospinal fluid, which showed a marked lymphocytosis. Investigation of spinal fluid shows, however, that this always results from postmortem changes, even a few hours after death, and cannot be considered as being of diagnostic value.[3] There were very marked granulations in the fourth, and scattered fine granulations in the lateral ventricles. The latter were somewhat dilated. The cerebral vessels showed no macroscopic changes. The convolutions, although small, were normal in appearance. The heart was small and weighed 280 grams. The tricuspid and mitral leaflets were slightly thickened and the mitral valve showed a slight atheroma and some stenosis. There were a few small atheromatous patches in the arch of the aorta and a slight hypertrophy of the walls of the left ventricle. There was a slight edema of the myocardium. The lungs showed a bronchitis with congestion, bronchopneumonia with abscess formation and pleuritis with a seropurulent effusion (300 c.c.). The microscope showed no evidence of tuberculosis in the lungs. The liver showed a slight congestion. The kidneys and adrenals were normal. The spleen showed a beginning amyloid degeneration in the Malpighian corpuscles, with some congestion of the pulp. The pancreas was normal. The vascular system showed no pathological changes.

Microscopic examination of the brain showed some congestion of the meninges. The piarachnoid showed a moderate infiltration by lymphoid and plasma cells. This infiltration, although present in all sections, was more marked in the left paracentral, right anterior central, right paracentral, second left frontal, and second right frontal convolutions, but was not excessive in any area. Plasma cells were observed in all of these sections and were present in the meninges of the cord, and their existence confirmed by the Unna-Pappenheim stain. Although not present in great numbers, they were quite uniformly distributed. There was apparently some increase in the number of vessels in the pia and a very noticeable increase in vascularity in the cortex. Many of the large and occasional of the smaller vessels in the cortex and subcortical regions showed a distinct infiltration by lymphoid and plasma cells in the adventitia and perivascular spaces. This was particularly noticed in the first right temporal and right anterior central regions. Many of the infiltrating cells appeared phagocytic in character and showed pigment. This infiltration of the vascular sheaths was moderate in amount and widely distributed, although many vessels were intact. Occasional rod cells (Alzheimer's *stäbchenzellen*) were found and satellitosis was quite marked. The neurones pointed in all directions and there was a very noticeable disturbance of the normal layering of the cortex. There was some neuroglia reaction in the molecular layer. The neurones themselves showed little degeneration, although there was some destruction of the chromatic bodies in the paracentral convolutions, with an occasional lateral displacement of the nucleus. The Weigert and Marchi sections of the medulla were negative. The meninges of the cord showed an in-

filtration similar to that described in the cortical pia. Occasional cells in the column of Clark showed an axonal alteration. The Weigert section showed a degeneration in the lateral pyramidal tracts which varied greatly in the different cervical segments. At some levels it was present on both sides, at others only on one side. In some places it was slight, in others quite marked and in some segments there was no degeneration at all. The posterior column showed somewhat similar changes. The same variation was present throughout the thoracic cord where there was a slight involvement of the direct cerebellar tract in some segments. At some levels the posteromedian and at others both the posteromedian and the posterolateral tracts were involved. The upper thoracic cord showed more marked changes than the lower, particularly in the posteromedian columns. In the lumbar cord there was a moderate degeneration of the posterior columns throughout, while in the lateral columns it was marked in some segments and slight or absent in others. There was a marked neuroglia reaction in some places, more noticeable in the posterior column. From a pathological point of view the extensive infiltration of the meninges of both brain and cord by lymphoid and plasma cells, the infiltration of the same character in the vascular sheaths, the disturbance of the layering of the cortex, the increased vascularity, the increase in the neuroglia elements, the presence of rod cells, the satellitosis, the degeneration of the cord and the ependymitis of the ventricles would seem to remove any doubt as to the diagnosis of general paresis. The mental condition of the patient can be explained on no other ground. In view of the involvement of the posterior columns of the cord, so frequently found in adults, it is reasonable to assume that the somewhat unusual lesions associated with a diffuse meningoencephalitis in this case are to be attributed to general paresis rather than a combination of that disease with some other affection of the cord.

ANEMIA, WITH SOME REMARKS AS TO ITS PATHOGENY AND HYPODERMIC TREATMENT.

By G. K. DICKINSON,

JERSEY CITY, N. J.

Anemia as a terminal condition in surgical states of continued hemorrhages presents interesting problems in morbid physiology which need to be comprehended before proper treatment can be instituted.

We are told that ordinarily metabolism of the iron-holding bodies is so carefully conducted that but little leaves the system. This is necessitated by the fact that the amount of iron in a being of average size is not more than fifty to fifty-five grains, and, owing to its importance, conservation is essential. The amount of iron in food runs from ½ to 1/6 of a grain a day, but it is so loaded with colloid material that its digestion and absorption are embarrassed. The portion of the intestine which has the selective power over the absorption of iron is the duodenum. Under the conditions of great demand, and if a considerable amount of iron be present, neighboring portions of the intestines and stomach are said to possess the power of absorption in a minor degree. As food iron has to be thoroughly acted upon by the gastroenteric juices before it may be absorbed, much may undoubtedly pass the duodenum without appropriation and be rendered inert for possible later absorption by the sulphur compounds lower in the gut. This may be the reason why the chloride in large doses seems to produce better results than iron administered in any other form, for it is in this condition that it more nearly resembles the end result of gastric digestion of food iron.

After passing through the intestinal epithelia this metal is found stored largely in the spleen as a granular pigment known as "hemosiderin." In the course of a week it will have passed from the spleen to the liver, where it is called "hepatic ferratin," to be delivered later as needed by the economy.

Iron is excreted to a slight extent through the urine, but the largest part through the cecum and continuous portion of the colon.

The synthesis of hemoglobin begins in the spleen and terminates in the red bone-marrow where the red blood corpuscles are formed.

In conditions where there is a constant drain on the blood-forming organs we see anatomical alterations in the bone-marrow, which is, next to the blood itself, the most unstable tissue in the body. In persisting hemorrhages the bone-marrow suffers widespread and profound degeneration supervening upon long and excessive activity, a state of exhaustion which may be attributed to long strain. It undergoes fibroid and gelatinous changes. The latter may be acute as well as chronic, characterized by progressive diminution of the blood-forming constituents and absorption of fat, the cells of which contain the latter undergoing myxomatous changes.

For some reason there may exist a duodenal insufficiency so far as iron absorption goes, due to inactivity of the epithelium or hormone defect, neither food nor medicinal iron being absorbed in sufficient quantity to stimulate the activities of the blood-forming organs; so that blood corpuscles stored with hemoglobin shall be formed. Medicinal iron will at times fail, through the production of gastric distress, pain, heaviness, anorexia, or diarrhea from intestinal irritation.

In order to circumvent the inefficiency mentioned, hypodermic administration seems reasonable. Glaevecke is recorded as being the first to introduce it in 1883, in the form of ferratum citricum oxydatum. His method has not received the general attention of the profession, in part because of failure to apply it in appropriate cases and by measuring its effect on the hemoglobin and blood count. Occasionally we will meet those in whom the iron salt produces a great deal of local irritation, marked pain, local tenderness, and subsequent painful nodes. Another sufficient reason to many is the large number of agreeable iron pharmaceuticals.

Clinically we may divide anemias into two types: that which is maintained by exhaustion of the duodenal mucosa and blood-forming organs, and that due to other conditions. In the former type where medicinal preparations fail, where the anemia cannot be relieved, and where the digestion is markedly embarrassed by medication, the hypodermic use of iron must be resorted to, no matter what its drawbacks may be. Kobert claims that iron

administered hypodermically may irritate the kidneys and produce a nephritis, but Cushny does not recognize this danger in therapeutic doses. In a fair per cent. of cases under treatment by this method considerable pain is produced, while in numerous others there is little or actually no pain.

The citrate of iron is not precipitated in the tissues, quickly passes into the circulation and is a most active bone-marrow stimulant. Two grains of the citrate are equivalent to .32 grain of free iron. A tartrate of iron and potash solution, of which two grains equals .30 grain of free iron, may produce a little less distress in an average run of cases. Other double salts and a succinate have been employed with very much the same result as to distress and recuperation.

Mr. J., age in the 50's, referred by Dr. W. L. Pyle, entered the hospital early in September, 1909; railroad man by occupation; past habits good. History of anemic attacks without apparent cause; debility, gastric, and enteric disturbances, partial recuperation each time by medication per os. Last recurrence the worst of all; mucosas and subungual places very pale; hemoglobin 20 per cent.; red blood corpuscles about 3,500,000, all in a condition of poikilocytosis. A diagnosis of pernicious anemia was made. Four grains of citrate of iron were thrown into the muscles of the shoulder, back, or thighs daily. There was some reaction as evinced by pain, tenderness, and an occasional serous accumulation (cystic.) Meantime, the tissues, being washed by a better blood, took on a stronger tone. His dyspnea ceased and strength came back so that he could walk all around the hospital, and at the end of six weeks his hemoglobin rose to 75 per cent., his blood count became normal and showed no distortion of cells. The duodenum resumed its normal function of iron absorption, and a physiological balance of iron metabolism has been maintained.

Mrs. M., age in the 30's, had been bleeding from an esophogeal angioma for seven years. These hemorrhagic attacks at the start would come every third month, lasting about a week, bringing down her blood content and tension to a point of faintness and dyspnea. As nothing controlled this peculiar cyclic condition, hemorrhages instead of being periodic and excessive, gradually ran together, blood being wiped from the mouth almost daily. Her heart became dilated, venous impulse ran up her jugulars, ankles became edematous, and she had all the other conditions incident to chronic anemia. Iron in any form or dilution did not activate her blood-forming organs. It would instead incite vomiting. Some peculiar tenacity of life kept her going. Good clinicians uniformly predicted death within three months. On September 1, 1909, the hypodermic use of iron was instituted, four grains daily being injected into the muscles. The first effect was an angioneurotic edema of the extremity used. After a week injections ceased to produce that reaction. Hemoglobin percentage, which was down to 12, immediately rose so that by the end of the sixth week it was 80. Her vessels became filled with a better quality of blood, and apparently there was an increase in quantity. Hemorrhages still continue, but come at their regular period of three months. Recuperation is prompt and effective. She has no dyspnea, heart has contracted, she does not suffer from indigestion, can walk long distances, and has resumed her position with family and society.

In closing, where loss of blood is continuous for a considerable time histological changes of a regressive type take place in the red bone-marrow. At the same time there seems to be a suspension of the function of the duodenal epithelia so far as iron absorption goes. Since September 1st this method has been employed on a number of seemingly appropriate cases. It is very painful to many, but, as it is their only hope, they have been compelled to submit to the pain in order to obtain recovery, which has been positive in each instance.

This article is submitted to the profession not as anything new, and simply to explain the condition in which hypodermic iron is of the most value and where this method of administration is absolutely necessary; also to emphasize the importance of continuance in spite of its unpleasant disturbances.

OBSERVATION ON DENGUE.

By NAGIB ARDATI, M.D.,

BEIRUT, SYRIA.

ASSISTANT TO PROFESSOR HARRIS GRAHAM IN THE MEDICAL CLINIC OF THE AMERICAN SCHOOL OF MEDICINE.

Dengue is a disease which was first described many years ago, but it is only since 1902 that we have begun to know more about it on an experimental and scientific basis. During a recent severe epidemic in Beirut, Syria, a city lying between the slopes of Mt. Lebanon and the Mediterranean Sea, I had the opportunity to study the disease and observed several interesting facts relating to its different phases, to which I would like to call attention. As the disease is confined to certain regions only, and not met with in others, I shall review briefly the whole subject in order to give a clear and thorough representation of it, taking into consideration the etiology, symptoms, and complications, with special reference to the last epidemic.

Dengue is an acute infectious disease of tropical and subtropical regions, characterized by fever, pain in the joints, bones, and muscles, sometimes by an initial erythenta and a terminal polymorphous exanthem. It comes in epidemics and in a short time attacks most of the inhabitants, only a few escaping it. Dengue epidemics are very common in Turkey, coming on in the summer and autumn and with varying virulence.

For many years nothing was known about the germ that caused it, and how it was carried from one person to another. Owing to the readiness with which it spread, direct contact and the air were blamed for its dissemination.

In 1902, however, Dr. Harris Graham, my chief, published a very interesting article titled, "Dengue, Study of Its Mode of Propagation and Pathology," Medical Record, Feb. 8, 1902, in which he cited his systematic experiments and observations and, beyond any doubt, demonstrated that dengue is transmitted from one person to another by a kind of mosquito, *Culex fatigans*. Further in his article he stated that he was able to see within some of the erythrocytes in fresh blood taken from dengue patients, small unpigmented bodies which possessed ameboid movements, and which, if watched long

enough, were seen to shift themselves from one part of the corpuscle to another. These bodies he took to be the parasites of dengue, and called them *Hæmamœba denguii*. Many investigators, however, searched for the parasite described by Professor Graham, but in most cases they failed to find it.

During the last epidemic of dengue, which lasted in Beirut about four months, I had the opportunity of examining the blood of many patients at different periods of the disease and in all the cases where I examined the blood carefully enough I did not fail to find the following results:

1. Fresh specimens examined carefully with the dark-field illuminator showed, in many erythrocytes, small, brilliant, light-reflecting bodies, which changed their shape, at one time appearing round, and at another fusiform, and moved freely in the blood corpuscles.

2. In specimens stained according to Giemsa-Romanowsky, I was able to find in the erythrocytes small, usually round, but sometimes elongated fine, granulated, from purple to blue colored bodies, of the size of 1-5 to 1-3 of a normal erythrocyte, occupying the margin, but also at times the center of the blood corpuscles. In some specimens these bodies seemed to be half way outside the corpuscles and in others to have completely left the erythrocytes, these latter, however, are sometimes difficult to differentiate from the blood-platelets. For the blood examination, special care was taken to select patients who never had had malaria.

The parasites I found, namely the bodies that were seen in the erythrocytes in the dark-field illuminator and in the stained specimens, were present in the blood of each case, showing clinically the symptoms of dengue, and they seem to be very similar to if not identical with those described by Professor Graham. It has been proved that dengue is transmitted by the *Culex fatigans*, and the disease has been experimentally produced in districts where it does not normally occur and where the culex is not found, by allowing mosquitos which have fed on dengue patients to bite healthy individuals in whom all the clinical symptoms of the dengue developed. The blood of such patients examined showed the presence of the parasite described above.

Taking these facts into consideration, together with the observations on the parasite above described, and its constant presence in the blood of patients clinically diagnosed as sufferers from dengue, I have no doubt but that this parasite is the cause of the disease.

The life history of the parasite is not easy to follow. At an early stage of the disease it appears in the erythrocyte as speck which enlarges and eats away the hemoglobin around it; and inside of 24 to 36 hours the speck reaches the size of about 1-5 a normal erythrocyte and fine granules appear in it.

About 60 hours after the beginning of the attack the parasite seems to reach its maximum size and begins to migrate out of the erythrocytes, usually by rupturing the latter. From this time on we find many parasites that are extracorpuscular and other intracorpuscular, as it were another crop beginning its cycle.

The extracorpuscular parasites look like a group of fine granules arranged more or less in circles, sometimes two or three of them lying side by side, each of them esembling a group of blood platelets. In the leucocytes are often found small granules which seem to show that the parasites were taken up by the white corpuscles.

Microscopically there are some points of differentiation between the dengue parasite and that of malaria.

DENGUE.	MALARIA.
1. Smaller.	Larger.
2. Usually round.	Different shapes.
3. Slightly pigmented.	More pigmented.
4. Finer granules.	Larger granules.
5. Less stainable.	More stainable.

The clinical symptoms of dengue in most of the cases were: after an incubation period of three to seven days there was a sudden onset, often with a chill, sometimes with vertigo and a high rise of temperature, accompanied by headache, bachache, pains in the joints, especially in the knees, and in all the muscles, and often pains in the eyeballs. There was usually an initial erythematous rash on the face and chest, which disappeared after the second day. In the course of the disease there often developed anorexia, tachycardia, and insomnia, and in some cases delirium.

The temperature was high, between 39° and 41° C. (103°-105.8° F.), lasted from three to six days, and terminated usually by a crisis, and with its fall there often developed a polymorphous exanthem, which rapidly faded away, occasionally with scaling of tne skin.

In some cases there was enlargement of the spleen. In the course of the disease some patients complained of chilly sensations and sweating. In some cases the symptoms were so mild that the patients did not even feel sick enough to go to bed. As to the duration of the immunity, it seems to last a few years.

Many authors writing on dengue say that it is a disease which runs a mild course, and is unaccompanied by any serious complications. The last epidemic, however, which we had in Beirut was accompanied by more or less serious complications, which I think are worthy of note. These complications were:

1. Hemorrhages into the skin, varying in size from that of a pin's head up to four or five cm. in diameter.

2. Alarming hemorrhages from the mucous membranes of the nose, stomach, and intestines. Two cases of hemorrhages from the nose and stomach terminated fatally.

3. Menorrhagia and metrorrhagia were observed in a number of instances.

4. Abortions in the fifth, sixth, or seventh month of pregnancy.

5. Severe gastrointestinal symptoms, pain, nausea, vomiting, diarrhea, and dysentery-like symptoms.

6. Heart infections, with two cases of myocarditis ending fatally in patients at the ages of 4 and 14, in whom before the dengue there were no symptoms of heart disease.

7. Typical conjunctivitis, which subsided with the end of the attack.

8. Edema of the skin, anasarca-like, which disappeared when the dengue was over; no heart or kidney trouble being present.

9. Relapses in about 15 per cent. of all cases, coming on after the second or third apyretic day; and in some cases even a second relapse had been noticed.

10. Protracted course, running two or three weeks, during which the patients have an irregular fever, malaise, lassitude, and inability to do any work.

MEASLES AND GERMAN MEASLES: CHARACTERISTICS OF THE PRESENT OUTBREAK IN PHILADELPHIA.*

By MAURICE OSTHEIMER, M.D.,

INSTRUCTOR IN DISEASES OF CHILDREN, UNIVERSITY OF PENNSYLVANIA.

The most striking characteristic of the outbreak of German measles and measles in Philadelphia this spring has been the fact that the eruptions in both of these diseases have been very similar, in fact almost identical. While, in some cases of German measles, the eruption has resembled that of scarlet fever, the great majority of these cases, adults as well as children, have had a rash which could not be distinguished from that of true measles. The other striking characteristic of both diseases has been the extreme mildness of the attacks; serious cases of measles have been rare, even when complicated by pneumonia.

The cases of true measles have been typical, with marked, even severe symptoms just before the rash appeared. But catarrhal symptoms always preceded the eruption, bronchitis, with coryza and conjunctivitis, being very common for some days or a week or longer; Koplik's spots have been observed also, in many cases. The great majority of cases of true measles have occurred in children who were known never to have had measles. The eruption has been profuse and has been visible for from five to ten days. Even these children with mild attacks have been in bed for a week or longer, though, in a great number of cases, no physician has been in attendance. In some young children pneumonia has been present almost from the beginning, the disease terminating fatally in some of these cases. Otitis media has also been a common complication.

German measles, on the other hand, has come on very suddenly, without any previous cough. A child or adult, generally one who distinctly recalls a previous attack of measles, is surprised to discover an eruption, which usually appears without any antecedent symptoms. In many cases enlarged occipital and cervical glands have been noted; in the majority no other physical signs could be elicited, the rash being the whole illness. In many young children, however, malaise, fretfulness, and anorexia were noticed. But inside of seventy-two hours all trace of eruption had disappeared, with a few enlarged cervical glands or nothing at all remaining.

In these cases of German measles in which the eruption simulated that of scarlet fever, the fact that the rash was limited to portions of the trunk or extremities, instead of spreading over the whole body, and the total absence of the other cardinal symptoms of scarlet fever, made the diagnosis easy. But when some throat condition, such as acute tonsilitis, occurred at the same time, or there was some gastric derangement with vomiting, the diagnosis was more difficult. The lack of a high temperature just before the eruption and of the fall of temperature after the rash has appeared; the relation between pulse and temperature; some known cause for the tonsilitis or gastritis, and the rapid disappearance of the eruption, without desquamation following, all helped to make the diagnosis clear.

Other eruptions have been confused with German measles, such as rashes due to strawberries, tomatoes, or other foodstuffs; prickly heat; insect bites, and eruptions resulting from drugs. In one confusing case, a colored girl, with a chronic eye condition which was under treatment, developed a scarlatiniform eruption, without other signs or symptoms; in fact she felt quite well. Investigation brought out the fact that her eye lotion had been increased in strength and the number of drops instilled into each eye doubled the day before the eruption appeared. On omitting the eye drops the flushing due to the increase of atropin at once disappeared.

In many of the cases of true measles a fine, branny desquamation has been observed over almost the entire body. Desquamation, like that due to sweating, has been most noticeable on the palms of the hands and soles of the feet, the skin coming off in tiny circular or irregular-shaped bits, from two to four weeks after the beginning of the illness.

Finally, the physician of Philadelphia must learn to differentiate between German measles and true measles, as it is his duty to report both diseases to the Bureau of Health. The present regulations call for a placard upon the front door of a house in which true measles exists, while German measles remains as yet unplacarded.

118 South Twenty-second Street.

*Read before the South Branch of the Philadelphia County Medical Society, May 27, 1910.

Excision of Adenoids and Tonsils.—Steinhardt mentions that a short time ago when the old diagnosis of intestinal inflammation was proved to be erroneous in many cases of abdominal pains and that symptom was called appendicitis it was the fashion to remove the appendix on the slightest provocation, but after the profession woke up very few appendices are now excised and then only for due cause. The same thing exists, in Steinhardt's opinion, in regard the excision of tonsils and adenoids, and as soon as the physician discovers that a child has them he jumps to the conclusion that the child must be nervous, etc. The worst thing is that most medical men believe the operation so simple that any one can perform it and the result is that more than two-thirds of the tonsils and almost all the adenoids remain after the operation. Steinhardt believes that when it can be proven that these glands retard the physical or mental development of the child, medical treatment should be instituted and, only when that fails we must recur to surgical means; but when we decide to operate the most radical procedure should be employed, as we frequently see that many operators leave large quantities of tonsil and adenoid tissue. Incidentally he records his belief that an anesthetic should be employed in all cases.—*Crónica Médico-Quirúrgica de la Habaña.*

Abuse of Forceps in Primiparæ.—A. Isaacson says that he believes it to be very unfair and unjust, non-professional, for a physician to apply the forceps simply because he is too busy and cannot wait for the natural forces to act or because he is envious of his brother physician and desires to lead in the percentage of forceps deliveries performed. A forceps delivery, even in the hands of the most competent, is, nevertheless, an operation which should not be taken too lightly; it surely does not add to the safety of the mother or child; and to subject a patient to this ordeal for selfish reasons only, as it is often done, constitutes, in his mind, a criminal act. It is not necessary to dwell upon the advantages of natural births, which are self evident, when we look upon the contrasting manifold disadvantages of forceps manipulations: (1) necessitating, as it does, the use of an anesthetic, most commonly chloroform, with its ordinary dangers; and it has been recently shown that chloroform always has a deleterious effect upon the liver; and there are cases on record of latent chloroform toxemias. (2) Manipulations increase the chances of infection. (3) The greater possibility of lacerations; and (4) lastly, but not of least importance, the dangers to the child in forceps application. With these great disadvantages staring into our faces, the author thinks the profession should limit the use of forceps only to cases indicated, and not merely use it at random or to please one's self. With conscientious consideration for the patients, our percentage of natural births in primiparæ would be greatly increased if the forceps was applied only where absolutely necessary.—*New York Medical Journal.*

SANITATION IN THE TROPICS.

THE work which, at the present time, is being done in various tropical countries has only been rendered possible by the results of the studies and investigations of many scientific men. In every tropical land malaria has been the chief disease which has stood in the way of the white man living and working effectively therein. The researches and practical labors of several men headed by Laveran, Manson, Ross, and Grassi have robbed malaria of most of its terrors. In addition to malaria, which is prevalent in all parts of the torrid zone, there are and have been many other even more deadly diseases, which are to a large extent restricted to certain regions. Among these may be mentioned bubonic plague, sleeping sickness, and yellow fever. Time was, not long ago, when yellow fever was a scourge of the West Indies, of South America, and of some portions of this continent, but the confirmation by the U. S. Army Board of Finlay's discovery that the mosquito was the means of spreading yellow fever and the practical application of this discovery by Colonel Gorgas put an end to yellow fever as a necessary menace to the inhabitants of the tropics. It was because of Gorgas' triumph in Havana that to him was entrusted the task of bringing order out of sanitary chaos in the Canal Zone. When the making of the canal had been decided upon it was freely recognized that the greatest obstacles in the path of its successful and speedy accomplishment were the unsanitary conditions prevailing in the Canal Zone. Havana had had a bad reputation, but that of Panama and locality was certainly no better. The country through which the canal had to pass was looked upon, and rightly, as a pest hole and a death trap. During the time that the French were working there the death roll among white men, yellow men, and negroes was appalling. Hence, the American Government viewed the project with some misgiving and apprehension.

However, from the standpoint of health all these fears have been dispelled, and now the mortality and morbidity rates of the white men on the Canal Zone are less than in most American cities. This reads like a fairy tale and the outstanding fact is not so much that the canal is certain to be a commercial success, but that proof has been afforded that the most deadly portions of the tropics can be made habitable and healthful for men and women of the northern races. This will be the true triumph of the building of the Panama Canal.

No expense would seem too great to attain the ends which have been attained on the Canal Zone. Indeed, as said before, the labors of Colonel Gorgas and coadjutors have perhaps alone rendered it possible to construct the canal. But as a matter of fact, the sanitation of the Isthmus has not been and is not nearly so costly as is generally conceived. At the meeting of the American Society of Tropical Medicine held in St. Louis in June, 1910, Colonel Gorgas read a paper (*Gulf States Journal of Medicine and Surgery*, July, 1910) dealing with the expenses necessary for sanitation in the tropics, in which he showed that the general opinion as to the cost of the sanitation of the Isthmus was greatly exaggerated and that really the sum devoted annually to this object was not unduly large. He computed that, reckoning the average population of the Canal Zone during the past five years as one hundred thousand, the per capita appropriation for sanitation in the same period was $3.38 per year, or 28 cents per month. The amount would not be excessive in any circumstances, and when the magnificent results from every point of view are borne in mind the sum seems trifling. The work of Colonel Gorgas and his associates is not only in the interests of this country but of humanity at large, and is such that money cannot recompense. Another important lesson, too, may be learned from the sanitary results in Cuba and Panama, and taken to heart by the inhabitants of many American cities. If a little of the energy and intelligence which have been expended in the cleansing of Panama had been put forth by the authorities of the Gulf cities in destroying mosquitos and improving sanitary conditions generally, the death and disease rates of these cities would be more satisfactory than they are at the present time. Still the Gulf cities are not the only sinners in sanitary matters in this country, and the example set by the Canal Zone sanitarian under most difficult conditions should incite civic pride throughout America to generous emulation.

ADRENALIN THERAPY OF MALIGNANT TUMORS.

BERLIN savants, at least those connected with the Imperial Institute for Cancer Research and Prof. Bier's University Surgical Clinic, continue to show plainly their belief in the possibility of finding at last a medical remedy for cancerous growths and malignomata in general. This is an encouraging sign, for surgical resources hold out no hope for attaining a permanent solution of the problem; so that no one should belittle earnest efforts to find new therapeutic adjuvants in the domains of physicotherapy and biochemistry. Certainly no one should fail to keep himself posted as to the work of von Leyden, Bier, and their numerous lieutenants. For if the problem of curing cancer still seems as far off as ever, knowledge has been greatly multiplied; and it is probable that the ultimate solution will rest on knowledge thus acquired rather than on

the "accidental discoveries" which some laymen are prone to credit for radical advances in medicine.

In the *Deutsche medizinische Wochenschrift* for July 21 Reicher of the Berlin Cancer Research Institute demonstrates that mouse-cancer (adenocarcinoma) responds to all the tests for human cancer, save that it is much more amenable to treatment. He explains this tentatively by the naturally short life of the mouse, which may imply a greatly lessened resistance of its tissue cells to remedial agents. Among the substances which may be made to cause the complete disappearance of mouse-cancer is adrenalin, when injected into the tissues surrounding the growth. The morbid tissue undergoes necrosis as the result of the injections. One's first impression would naturally be that adrenalin therapy represents a starvation treatment through the characteristic action of the drug on the blood-vessels. The author, however, does not allude to this possibility and, in fact, his vain endeavors to immunize animals against inoculation-cancer by preventive injections of the drug show a belief in a specific property of the latter. To transfer the adrenalin possibility from the mouse to man, in view of certain alarming consequences sometimes attributed to systemic injections of the drug, is to assume some responsibility. Adrenalin has been pronounced contraindicated in a variety of degenerative diseases and certain other disorders, because of its action on the blood pressure. It is true that it would be injected for its local effect—and in the trifling amounts employed for local anesthesia unpleasant consequences are not feared; but if employed systematically for weeks at a time, enough might be absorbed to affect the blood pressure unpleasantly. This could in part be offset by physiological antidotes.

Reicher announces, moreover, that he has already tested adrenalin on human cancer with encouraging results. His forthcoming report will be awaited with interest.

Cause of Beethoven's Deafness.

Surprisingly little has ever been learned concerning the physical basis of this great composer's gradual and complete loss of hearing. It is naturally much easier to determine what was not instrumental in causing it. We may, of course, state that the lesion involved was a progressive otosclerosis, but this expression throws little light on the nature of the process in his particular case. Any acute or chronic infectious disease may, or might in theory, give rise to otosclerosis as a complication. Dr. Jacobsohn of Charlottenburg has discussed the subject of Beethoven's malady quite compendiously in the *Deutsche medizinische Wochenschrift* for July 7 and gives all the data obtainable, along with a brief list of references drawn from varied sources. There is some evidence that the composer had "abdominal typhus" about a year before his hearing gave way. But little was known of typhoid at that time—it had not been differentiated from pestilential typhus. We know to-day that typhoid is a not infrequent cause of otosclerosis. There is absolutely no evidence that the composer had ever contracted syphilis, but attempts have been made to show that his skull formation was suggestive of congenital syphilis; nothing was found at his autopsy to indicate that he had ever suffered from this malady. Although he died with cirrhosis of the liver, there was not sufficient evidence to show that he was an alcoholic. He had had smallpox in early life, but so had approximately half of all his neighbors. By exclusion, therefore, Jacobsohn is inclined to regard typhoid fever as solely responsible for the lesion which transformed a naturally cheerful and optimistic individual into a crabbed misanthrope. The accident brought out heroic qualites in the man, but Dr. Jacobsohn does not venture to express an opinion as to whether the sufferer's art was a loser or gainer through his misfortune.

Electrolytic Arrest or Cure of a Malignant Epithelioma.

For a generation or thereabout electrolysis and other methods of electrotherapy have made distinct headway against forms of tumor which, while not technically malignant as a class, have been progressive and often inoperable, including fibrosarcoma of the nasopharynx, cavernous angiomata of the tongue, and the like. Actual malignant growths have been amenable as a class to such treatment only when very small, as in the earliest stages of relapses in localities where wide incision is impracticable. Occasional results are obtained where the prognosis under such treatment would not have been called in the least encouraging. Kafemann reports a case of this kind in the *Deutsche medizinische Wochenschrift*, June 30. To use the author's own method of summing up, he states that he had to do with a very far advanced case of epithelial cancer of the nasopharynx with numerous glandular metastases on both sides of the neck. The growth, three months after surgical removal, suffered a violent relapse. The recurrence was first curetted and then treated for thirteen sessions with electrolysis, with the result that the tumor cells appeared to have lost their power to proliferate. The case was watched for two full years and no renewed activity was manifested. Certain pathologists would doubtless explain this result by the activating of the defensive leucocytes, by the formation of enzymes hostile to cancer growth, or by the stimulation of the young connective tissue cells which should normally possess the power to antagonize the growth of cancer cells. The author believes that reports of similar recoveries occur in the older literature, and either escaped fair notice or were received with incredulity.

Treatment of Rheumatism by Bee-Stings.

Some years ago bee-stings were advocated by a medical man in the Isle of Wight as an efficient remedy in the treatment of rheumatism. Latterly, little has been heard of this somewhat unusual and heroic treatment, and that it had ever been thus employed had probably escaped the memory of most physicians. However, recollection has been stirred by an article which appeared in the *Lancet* July 23, extolling the merits of the treatment. Dr. F. H. Maberley writes to that journal to say that the results from the employment by him of bee-stings in the treatment of rheumatism have been attended by conspicuous success. He cites a large number of cases, in which great relief has been obtained by these original methods. With regard to the mode of applying the insects he writes as follows: "In elderly people it is better to start with

about six stings for the first three applications, when they may be gradually increased even up to a couple of dozen. Sickness often supervenes if too many are put on at first. There is a little difficulty for a novice in putting them on, but I have perfected a pair of forceps which, while preventing injury to the bees, holds them firmly. The stings should remain in for a few minutes before removing them. In old standing cases treatment will have to be continued for many months." Dr. Maberley says that if this form of treatment does not effect a complete cure it gives relief in almost hopeless cases. There are doubtless many sufferers who would willingly allow themselves to be stung by bees if by such means respite from pain could be obtained. It is therefore encouraging to learn on good authority that the sting of bees has a deterrent influence on the course of rheumatism.

News of the Week.

Straus Milk Depots.—Because of the persistent attacks made upon him by a newspaper in New York, it is said, Mr. Nathan Straus has announced that he will not continue his free stations for the distribution of pasteurized milk in this city after the close of the present season. Believing that the criticisms are merely personal, Mr. Straus hopes that upon his withdrawal the city authorities will be compelled to take up the work of supplying pasteurized milk to needy babies, and that the charity will thus spread even more widely. During the present season Mr. Straus has maintained seventeen stations in the city, the annual distribution being about 4,000,000 bottles of milk. In addition to these seven stations are maintained during the summer, approximately 1,500,000 glasses of milk being served to all comers. It is said that the work will be continued by Mr. Straus in other American and foreign cities.

Charitable Gifts.—The Presbyterian Hospital receives a bequest of $7,500 to found a bed in perpetuity, under the will of the late Mrs. Harriet Coles of Glen Cove, L. I.

The New York Academy of Medicine receives under the will of the late Mrs. Margaret E. Gray a bequest of $50,000 to establish the Landon Carter Gray memorial, in memory of her husband. The income of the fund is to be used from time to time in purchasing books for the library of the academy.

A Ruling Against Osteopathy.—Justice Putnam of the Brooklyn Supreme Court, on August 26, handed down a decision in the case of Charles F. Bandel, an osteopath, who applied for a mandamus to compel the Board of Health of New York to grant a burial permit on a death certificate signed by him. Justice Putnam upholds the demurrer of the Corporation Counsel, and sustains the action of the Board. In a memorandum accompanying the decision Justice Putnam says: "While the State has wisely allowed the practice of osteopathy, it does not follow that it thereby holds out one, without any practice in surgery or experience in prescribing drugs, as fully qualified to certify the cause of death. Indeed it is not certain that a board of health would be compelled to take the certificate of death of all licensed physicians in the event of an epidemic or the spread of some new and mysterious disease. Granted that the theoretical education of the osteopath is of a standard equal to that of a doctor of medicine, after he enters on his profession his practice is restricted, so that it does not appear that he can make the tests by examination of blood and tissues by which alone many diseases can be certainly detected. The sanitary code is discriminatory, but the discrimination is not personal and arbitrary. It is based on a limitation which the osteopath may be said to make for himself, and deprives him of no rights which he ought to exercise consistent with the public safety."

Cholera in Europe.—An improvement in the cholera conditions in South Russia is shown in the latest reports. For the week beginning August 14 the Sanitary Bureau reported 16,106 new cases, with 7,743 deaths, the figures being several thousand below those for the previous week. The total figures for this epidemic in Russia up to August 21 are given as 121,091 cases and 58,030 deaths. The appearance of the disease in Vienna is reported, the victims being recent arrivals in that city from Hungary. In Roumania it has been thought advisable to omit the annual maneuvers of the army because of the numerous cases of cholera along the frontier. A number of new cases have also been reported from the province of Bari in Italy, cases are reported from Spandau in Prussia, and several suspicious cases have been discovered in Berlin.

Epidemic Poliomyelitis.—Dr. Simon Flexner of the Rockefeller Institute has issued a request for specimens of the nervous system from fatal cases of epidemic poliomyelitis, which is widely prevalent throughout the United States and Canada at the present time. The specimens should consist of portions of the spinal cord, preferably of the lumbar or cervical enlargement, removed as soon after death as possible, and preserved in plenty of pure glycerin. The specimens are to be used for experimental purposes, and may be sent by mail or by express collect to Dr. Flexner at the Rockefeller Institute, Sixty-sixth street and Avenue A, New York.

Race Suicide in Hawaii.—According to a report made recently by Governor Frear of the Hawaiian Islands, the birth rate of Hawaii is decreasing in proportion to the population, while the death rate is increasing. Last year the deaths numbered sixty-one more than the year before, whereas the births numbered 600 less.

New Offices for Coroners.—The Board of Coroners of Manhattan Borough, New York, will move shortly from its present quarters in the Criminal Courts Building to 75 Lafayette street, which has been leased for the purpose.

A Lutheran Hospital.—The Lutheran Inner Mission Society of New York is working to establish a new hospital to be especially for the Lutherans of the city. The society has already established a district medical service, having for this purpose divided the city into fifteen districts, each in charge of a physician who responds to calls sent by the workers in Lutheran churches to treat cases of needy persons.

Germ-Proof Bills.—The National Bank of Spokane, Washington, announces the issuance of the first antiseptic, germ-proof National banknotes. Fifty thousand dollars in bills recently sent out were printed with ink consisting largely of carbolic acid.

The Southeastern Wisconsin Physicians' Association at its seventh annual meeting held at Racine on August 17 elected the following officers: *President*, Dr. Edward Kinne of Elkhorn; *Secretary and Treasurer*, Dr. Milton V. Dewire. The next convention will be held at Elkhorn.

Mr. Gustave Moynier, President of the International Committee of the Red Cross since its foundation in 1863, died at Geneva on August 22, aged 84 years.

Obituary Notes.—Dr. John Wells Bulkley of Washington, D. C., a graduate of the Berkshire Medical College (Medical Department of Williams College), Pittsfield, Mass., in 1844, and one of the oldest practitioners of the District of Columbia, died at his home on August 23, aged 87 years. Dr. Bulkley was one of the first physicians to attend President Lincoln after he was shot, and remained with him until his death.

Dr. Joseph Janney Hull of New York, a graduate of the Medical Department of New York University in 1858, a member of the New York State and County Medical societies, the New York Pathological Society, and the New York Hospital Alumni Association, and consulting physician to the Nursery and Child's Hospital, died at his home on August 26, aged 76 years.

Dr. Paul Cheseborough Skiff of New Haven, Conn., a graduate of the Yale Medical School in 1853, and a practitioner of medicine in New Haven for over forty years, died in that city on August 26, aged 82 years.

Dr. Francis Collamore of Pembroke, Mass., a graduate of the Dartmouth Medical School in 1847, died at his home on August 18, aged 84 years.

Dr. Samuel B. Littlepage of Oakland, Cal., a graduate of the College of Physicians and Surgeons of Keokuk, Ia., in 1885, died on August 11, aged 72 years.

Dr. B. Wagener Hunter of Charleston, S. C., a graduate of the Medical College of the State of South Carolina in 1894, and a member of the Charleston Medical Society, died at his home on August 13, aged 47 years.

Dr. John W. Klein of Louisville, Ky., a graduate of the Hahnemann Medical College of Philadelphia in 1871, died at his home on August 13, following a stroke of apoplexy, aged 59 years.

Dr. Wilson N. Heflin of Roanoke, Ala., for many years a practising physician in Randolph County, a graduate of the Medical College of Georgia in 1851, died at his home on August 13, aged 82 years.

Dr. Wellborn Calhoun of Atlanta, Ga., a graduate of the Jefferson Medical College in 1869, Professor of Diseases of the Eye in the College of Physicians and Surgeons of Atlanta, a member of the Georgia State and Fulton County Medical Societies, and attending surgeon to several hospitals, died at his home after several months' illness on August 21, aged 65 years. Dr. Calhoun was a veteran of the Civil War, having served in the Confederate Army.

Dr. William B. Stewart of Unadilla, N. Y., a graduate of the Vermont Medical College of Rutland, a member of the Vermont State and Bennington County Medical Societies, and until recently a practitioner in Bennington, died at his home on August 21.

Dr. Robert Amory of Boston, Mass., a graduate of the Harvard University Medical School in 1866, formerly lecturer on Physiology and the Action of Drugs in this school, and later Professor of Physiology in the Medical School of Bowdoin College, and the author of several works on physiology and therapeutics, died at his summer home at Nahant, Mass., on August 27, aged 68 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

BRITISH MEDICAL ASSOCIATION—THE MUSEUM—BACTERIOLOGY TYPHOID CARRIERS—EFFECT OF ALCOHOL ON NERVE TISSUE—SOURED MILK TREATMENT—OBITUARY.

London, August 12, 1910.

The immediate effect of the British Medical meeting seems to have passed into the limbo of yesterday's forgotten news or to have evaporated with the excitement of the entertainments and hospitalities; or, as one says, become "ancient history," and so no longer talked about or edged out of conversation by later events. But the serious side will, of course, have its influence. The meeting was well organized to secure publicity; indeed, as an advertisement, could not be bettered. Discussions on sociology and semi-political topics were well adapted to draw the lay press in the dead season, and were so far successful. It was rather curious in a medical meeting to hear speakers interrupted by "cheers" or "yes, yes" and "no, no," as happened in the debate on the falling birth rate, as to which acute differences of opinion were expressed by members more or less competent to discuss such subjects. But the notice of the newspapers was obtained, and even the genial Mr. Punch remarked that if the arrival of a baby is really so rare, might not the Mayor of the locality formally wait on every newcomer and welcome it to the community with the hope that the arrangements made for its reception will give it complete satisfaction.

One of the best things connected with the meeting was the museum arranged in nearly twenty departments. Of these those illustrating tuberculosis and cancer research were perhaps most attractive to practitioners, but bacteriology generally was well represented. So, too, were most of the sections, each under a separate curator. The collection must have cost an immense amount of time and care by many experts, and it seems a pity that it should have only been available for three or four days, when the visitors had so little leisure to examine the exhibits.

The bacteriologists mustered well in their section, and their president (Dr. C. J. Martin) suggested that physicians and health officers might do well to consider more carefully man as himself a propagator of disease. In diphtheria prevention it would, if practicable, be more effectual to shut up contents with burning sulphur than to turn them out and fumigate the room.

Dr. Houston then opened a discussion on recently obtained knowledge of pathogenic organisms bearing on disease prevention. He thought passive transmitters—soil, food, water, air—had been too exclusively studied and the living storehouses of bacteria rather neglected. Soil does not seem to feed the bacteria, which, in fact, are gradually destroyed in it. Even in water, which he admitted was a transmitter, the bacteria tend to lose vitality—not to multiply. Solid food did not play a large part in propagating diseases, though vegetables grown in polluted soil and fish in polluted water eaten uncooked were possible transmitters. On the other hand, in liquid foods multiplication may take place. He did not say dead matter played no part in contagion, for it was well known that soils infected by tetanus and anthrax were almost permanently dangerous.

He held that living carriers were of the greatest importance, for typhoid is not the only disease which is distributed by them. Indeed, the question might well be discussed how far infectious diseases generally were so conveyed. Perhaps the nation might not be spending too much time and money on the purification of contaminated materials, the protection of the uncontaminated, and the avoidance of dangerous surroundings. But too little attention was given to the attempt "to discover and render inoperative the living storehouses and factories of disease." The hope of progress in preventive medicine was based on this study.

Prof. Otto Linz read a paper dealing with this question of carriers in epidemics of typhoid, and said it had been shown that the bacilli might persist for years in as much as 4 or 5 per cent. of all cases. Many cases owed their infection to them, but not so many as might seem likely, as most of those around the carrier would suffer either severely or mildly, and so the community become immune.

In a paper on dysentery carriers it was stated by Drs. Macalister and Menzies that the disease is only propagated by convalescing patients, not by those perfectly recovered.

Dr. Arkwright said that in diphtheria 50 per cent. of cases are free from bacilli two or three days after the

exudation has disappeared, but, on the other hand, in hundreds of cases convalescents had been found to harbor nonvirulent strains.

Prof. McWeeney mentioned a case of a carrier who during seven years had infected a number of persons.

Dr. Buchanan remarked on the difficulty of ridding the gall-bladder and urine of bacilli.

In reply Dr. Houston admitted that the weak point lay in lack of proof that bacilli in carriers could provoke epidemics.

Radium gave its name to a section in which important statements were made. Its value in cancer was, of course, discussed. Dr. Louis Wickham of Paris, who has carried on extensive researches in this matter, did not confine his appearances to a single section, but a rough summary of his views may be gathered from several sources. He claimed to have treated about 600 cases, and though he could not speak of radium as curative, he believed it may prove of service in the treatment of disease. Thus it could render operable cases which were inoperable, and could consolidate the subsequent cicatrices, but it must be controlled by those with experience. The limitations to its use were great—inaccessibility or vital nature of parts involved, advanced age, etc.—but still an expanding field was open to the surgeon. If five years elapsed after operation for cancer without recurrence, he considered it cured, though this was not fully accepted by the profession. He believed if malignant growths were excised at an early stage they would be cured. He did not, however, define the exact stage, and he did not therefore show how they could then be recognized.

Sir J. J. Thomson, the great physicist, who disclaimed medical knowledge, gave a most interesting address in which he attributed the injurious effects of *x*-rays to the soft ones only, but suggested that as they were the more readily absorbed their mode of production should be studied. It was very difficult to get them from the Roentgen tube, but under some conditions secondary radiation might obtain a definite softness, as shown by Barkla. Metals when struck by *x*-rays gave out a special quality which was constant for the metal, so he suggested that the radiation from some metal would probably give out soft radiation of a definite value for medical use, and would be more easily obtained than from the Roentgen bulbs.

Drs. Dominici and Warden of Paris showed eight patients who had been brought to London to give an opportunity to the surgeons to satisfy themselves of their cure.

Dr. Freund advocated the removal prior to applying *x*-rays of all crusts and scales which might hinder penetration.

The effects of the rays on the brains of growing rabbits were stated in a paper by Drs. Turner and George, which led to some talk about the treatment of ringworm and its possible danger. Opinions differed. Some members also contributed instances of the value of the rays in diagnosis, especially in fractures and diseases of bones. It was also useful to corroborate a diagnosis, such as calculus. The organization of an *x*-ray department in a general hospital was described by Dr. Simmons. Dr. Lazarus Barlow described his recent researches at the Middlesex Hospital cancer department. Dr. Barclay of Manchester illustrated by radiographs affections of the stomach. Others discussed the appearances of phthisis, active and healed, under *x*-ray examination.

So much has been said and written on the questions relating to alcohol that it was a relief to hear Dr. Mott say he would rather give a demonstration than read a paper on the subject he was announced to bring forward—"The effect of alcohol on the nervous system." Accordingly, he showed a number of lantern slides to illustrate such points as the wrist-drop, the degeneration and destruction of nerve fibers in varying degrees, changes in sensory cells, neuritis of the vagus, hemorrhage into the brain from degeneration of the middle coat of an artery, and so on. He dealt to some extent with the mental symptoms of alcoholics and defectives, and said he thought alcohol and imbecility combined in parents led to insanity in the offspring.

Sir C. Allbutt divided alcoholics into spasmodic drinkers and regular boozers. The former seemed to be assailed with sudden desire and displayed no remorse for their conduct, in some points resembling epileptics.

Mr. Shattock questioned if they would experience the desire if they had never tasted alcoholic drinks.

Dr. Passmore said one of the slides showed definite mischief in the brain, and he was of opinion that all chronic alcoholics were eventually affected, though they might not have visceral disease.

Dr. McVicar had observed that the mental symptoms of alcoholics were like those of senile degeneration.

Dr. Willcox gave an account of the plan of employing oxygen mixed with the vapor of alcohol devised by himself and Prof. Collingwood. The oxygen was passed through absolute alcohol before being inhaled, and appeared to take up a definite amount of alcoholic vapor, and so greatly enhance the effects of the gas. Cases of cardiac failure where oxygen alone produced no effect had been restored, it was said, by this mixture. In emergency a wash-bottle with inlet and outlet tubes could easily be utilized.

The soured milk treatment has had such a run in London that one naturally looked for a good discussion of it in the therapeutical section. Dr. Grünbaum dealt with the theory involved, and said the bacilli formed the acid just where it was wanted. The *B. bulgaricus* was more active than others and easily distinguished from other organisms. He gave the milk just at the stage when it curdled. Mucous colitis cases benefited, but gastric cases did not. Putrefactive toxins were neutralized. Uremia and diabetes he thought sometimes had improved.

Prof. Hewlett testified to the superiority of the *B. bulgaricus* over the other lactic acid-producing organisms, and related experiments as to the value of some preparations. He found tablets inefficient and uncertain as ferment starters.

Prof. Vaughan Harley's experiments convinced him that soured milk given by the mouth reduced intestinal putrefaction.

Dr. Bryce referred to the disadvantages of the remedy he had noticed, viz., constipation, aggravation of acid dyspepsia, and rheumatic complications.

Prof. Sahli had seen benefit in acidosis, and he attributed the effect to lactic acid, which he had given by itself. The dose was thus easy to regulate.

Dr. Robert Hutchison preferred ordinary intestinal antiseptics to this soured milk treatment which had become a popular craze.

Dr. Bond said whey was the best medium of lactic acid, as the casein was got rid of. Whey might be freely taken, for it did not cause dyspepsia, and was, moreover, a good cardiac tonic.

Prof. Bradbury had found the lactic treatment useful in cardiac irregularity and bradycardia.

Dr. Hertz had seen severe diarrhea produced. On the other hand, it had relieved constipation. Acute infection of the colon was benefited. It was proper to control the secretion under bacteriological examinations while giving the lactic acid treatment.

Dr. Wm. Berry, J.P., F.R.C.S.I., Senior Surgeon to the Royal Infirmary of Wigan, where he had lived for many years and was a prominent citizen as well as a practitioner, died on July 29. He had been a guardian of the poor and a municipal councilor, and was made a justice of the peace. He was a good all round practitioner as well as a skilful operator. The president of his college was represented at the funeral, as were various local authorities and the profession.

The death of Dr. Danford Thomas, coroner for Central London for some thirty years, removes a prominent figure from the public life of the metropolis. A few years ago he remarked that he had held several hundred thousand inquests. In his long career he had carefully studied the facts of criminology, and a number of his suggestions have been embodied in our law. He had never quite recovered from a seizure a year or two ago, and last week a second closed his career. As a barrister as well as a doctor he was eminently qualified for the office he so admirably filled.

Dr. Wm. Spence, who died on the 27th ult., after an operation for appendicitis, in his fiftieth year, leaves a widow and four children. He had practised in Dollar most of his career, and was greatly esteemed. He spent last winter in Davos, and returned, as was thought, much better for the change and rest.

The death of Dr. Mary A. Marshall at the age of 74 recalls the early days of woman's entrance into the profession in modern times. She took her degree of Doctor of Medicine at the University of Paris in 1879, and the Science of the Royal College of Physicians in Ireland in 1890. She became Senior Physician to the New Hospital for Women.

The death is reported from Southern Nigeria of Dr. A. B. Sigismond Powell, of the Medical Department of that Colony, who at the time of his decease was quartered at Forcados.

Dr. Ernest D. Simpson, I.M.S., died in India on the 1st inst., of cholera. He was only 28 years old, and was to have been married next month. At school and the University of Edinburgh he was noted as a steady worker and a leading athlete.

OUR LETTER FROM VIENNA.

(From Our Regular Correspondent.)

THE URINE AS A TEMPERATURE INDICATOR—A MILLIONAIRE RUINED BY MEDICAL FEES—AN AIR-SWALLOWER—THE ENZYME TREATMENT OF COLD ABSCESSES AND SEROUS EFFUSIONS—GANGRENE OF THE LUNGS—606.

VIENNA, July 23, 1910.

MARTIN ENGLANDER has constructed a urine thermometer, an apparatus for the determination of the body temperature from the freshly discharged urine. This consists first of a celluloid funnel, with an aperture for the penis. The celluloid is neither influenced by the air or moisture, and its camphor smell covers that of the urine. Within the celluloid funnel is a smaller one of cork, which prevents the radiation of warmth from the urine. Inside the cork funnel is placed for each measurement a new filtering funnel, with an accurately dimensioned opening for the escape of the urine. The cork and filtering funnels make it possible to obtain fully trustworthy temperatures with a maximum thermometer fixed opposite the aperture in the celludoid funnel with the aid of a detachable clamp; this quite independently of the room or surrounding temperature. Parallel measurements between the urine and axillæ show that the axillary temperatures, especially in actual and suspected consumptives, do not give the diagnostically important subfebrile and high subfebrile temperatures, but in many cases, normal values only.

Prof. Dr. Herm. Schlesinger presented before the Gesellschaft der Aerzte an American patient—a former millionaire—who had become impoverished as the result of the expense entailed in the treatment of a painful malady. The case was one of aerophagy, for which a gastroenterostomy had to be done. For seven years patient had suffered from extremely frequent pains in the gastric region, and had already been laparotomized four times. The attacks persisted, however, and were only mitigated from time to time by hydrotherapy. Patient had employed for the individual attacks large doses of morphine and chloroform, had been narcotized several hundred times without any disadvantages, and had used morphine and scopolanin in doses regarded as lethal. In all his attacks pains first appeared, followed suddenly by a firm, smooth tumor in the region of the stomach, whereupon the pains became unendurable. The tumor represented the sudden distention of the stomach by the swallowed air; this vanished under narcosis, and the attack was at an end. The air could not be withdrawn with a stomach sound. As patient expressed the intention of suicide, a gastric fistula was established as a last resort, which is ordinarily closed. When patient notices an attack coming on he opens the tube and the gas escapes, so that no attack develops.

In the Gesellschaft für Aerzte, N. Schiller spoke on the ferment treatment of cold suppurations and serous effusions. The nature of the treatment is that pure ferment solution is applied to the abscesses so that the accumulated non-absorbable albumin may be broken up into soluble substances, and the stagnation removed with promotion of absorption. As ferment solution Schiller and Jochmann first used only the pure leucocyte enzyme; later, as a result of further study, it appeared that the leucocyte ferment could be replaced completely in its chemical properties by trypsin. The preparation is a reddish gray powder, relatively easily soluble in water. A 1 per cent. sterile solution is used for injection, and this because of slight stability must be prepared fresh daily. Physiological saline solution serves as a solvent. The technique of injection is as follows: After previous cleansing of the puncture site the abscess is punctured with a strong needle and the contents either aspirated or expressed. It is recommended to make the puncture opening a little to one side of the abscess, and not at its most dependent point; as in the latter case a fistula will result, through which the newly collected pus will continue to seep. Cold abscesses are very favorably influenced by the ferment treatment, and at times heal with surprising rapidity. It has been shown to be very useful to empty the abscesses daily and use the trypsin solution every second day. In abscesses up to the size of a hen's egg, Schiller, as a rule, injects from 2 to 3 cm. trypsin; in larger ones from 3 to 4 cm. A light compression dressing is always applied. As a rule, three or four injections suffice. Of tuberculous lymph nodes Schiller has only treated the softened ones, and with success. On the other hand, tuberculous joint affections are very refractory to the treatment. Serous effusions are very favorably influenced by the latter. Ganglions vanish ordinarily after a single puncture and injection. The same holds good for bursæ mucosæ (bursitis prepatellaris), and in these cases, the author said, he had often seen excellent results follow the institution of the ferment treatment.

Primarius Lotheisen demonstrated in the Gesellschaft der Aerzte a 45-year-old female subject, upon whom he had operated for extensive pulmonary gangrene. The woman first suffered from pneumonia, was strongly pulled down thereby, and finally had foul-smelling sputum, with coincident rise of temperature. She was brought to the hospital, where to the right side, close by the spinal column, a locality was found with amphoric respiration, coarse rales—in short, with cavitary symptoms. In the dependent region was empyema, as confirmed by trial puncture. Radiography showed darkening of the right half of the thorax, with a clear area at the fifth and sixth rib, medial at the scapula, over which a still clearer area was visible. This was a gangrenous focus, with an air bulla. The woman was almost too weak to submit to examination; she became cyanotic, temperature 39.4 degrees C. Under local anesthesia the empyema was evacuated below the eighth rib. As had been supposed, this did not communicate with the gangrenous cavity, but was separated from the latter by a bridge about 5 cm. thick. Thereupon, under Schleich's anesthesia, the sixth rib was resected from the process outwardly to the extent of 7 cm. A sclerotic lamina, 1.5 cm. thick, partly pleura and partly lung tissue, now had to be divided in order to enter the gangrenous cavity, which was larger than the first, and contained gangrenous shreds (histologically lung tissue) and pus having a carrion odor. At the base was the lumen of a large bronchus, the size of a heller, which, previous to the operation, had been drawing off 70 cm. sputum daily. The cavity was tamponned and drained externally, and the sputum at once lost its gangrenous smell, and in a few days came down in amount to 20 or 30 ccm. The empyema quickly healed under aspiration drainage. The gangrenous cavity closed more slowly. It is interesting to note that the bronchial fistula closed without a second operation (suture is often required); it was sufficient in this case to cauterize the lumen often with nitrate of silver stick. The granulations which shot up about the lumen were incited to more rapid growth by the application of tincture of iodine.

The Ehrlich discovery as to the cure of syphilis has naturally caused a justifiable sensation among us. Several reports of clinical investigations have already been made.

Walter Pick reported on over thirty cases of syphilis treated by the Ehrlich-Hata preparation No. 606. Ehrlich found that after a single injection into the gluteal musculature the visible symptoms vanished in strikingly brief time. This was true of both early and late symptoms, and also for malignant syphilis which had proved refractory to mercury. Pick himself saw a large ulcer in the pharynx and a gumma of the forehead heal in fourteen days. In a second case, fourteen days after an inunction cure, papules appeared on the tonsils and disappeared in five days. Secondary symptoms disappeared most rapidly of all. Wassermann's reaction was not influenced thereby. Injurious collateral effects were not observed, but the injections caused pain, which lasted four or five days, and also a temperature rise to 39 degrees C. Pick summed up his experience as follows: The Ehrlich remedy does excellent work in causing the symptoms of syphilis to disappear; but whether or not it is a cure must be shown by further observation.

Rudolf Doerr corroborated the basic idea of the new therapy, which is the sterilization of the body by a single injection, *i. e.*, by the destruction of the spirochetes. This is best accomplished by intravenous injection. Doerr has in several cases made intravenous injection of from 0.1 to 0.25 g. Only four hours later a short fever appeared. Twenty-six cases were treated with intragluteal injections of 0.3 to 0.4 g. Threatening phenomena never appeared. Fever and tenderness at the site of the injection developed, but these became less marked when the new methyl alcohol preparation was substituted. There is no connection between the fever and size of the dose, which Doerr has now brought up to 0.5—0.6 g. The therapeutic results are as follows: Scleroses recede, secondary symptoms fail to appear. When the latter are already present they disappear for the most part in a week, and cases treated for from one to four weeks have not relapsed. Two cases of syphilis—one a universal crustous syphilis with fever and night sweats, and the other one of deep ulcerations the size of the palm—which had proved refractory to all previous treatment—were promptly benefited by the injections. Among the old syphilitics treated were five cases of paralysis; after injection of 0.4 g. there was improvement in the vertigo, paresthesiæ, and lack of attention.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 18, 1910.

What Is the Experimental Basis for Vaccine Therapy?—Theobold Smith gives a very brief sketch which is significant in showing the rapid march of events from vaccination before exposure to protect from an impending infection, to vaccination after exposure and even during the course of an acute disease. Experimental medicine has very little to offer which is of service in deciding upon the efficacy or harmfulness of vaccination during disease. Vaccine therapy or therapeutic vaccination is simply an offshoot of prophylactic vaccination; one shades insensibly into the other. The principles underlying prophylactic vaccination are applicable to vaccine therapy. Animal experimentation has taught that immunity and susceptibility are purely relative terms. Immunity has been shown to consist of a series of cooperating and interacting forces represented by antitoxins, bacteriolysins, opsonins, agglutinins, and phagocytosis. The discovery of the different antibodies has not thus far been of much assistance in practically gauging the value of vaccines or making them more effective, if we except the measurement of the opsonic index as devised by Wright. He pictures the difference between prophylactic and therapeutic vaccination. If an animal is injected with a given dose of living or dead bacteria, this animal is protected against a subsequent inoculation which would have been fatal to an untreated animal. The vaccination has put the body in a state of preparedness, probably by increasing the supply of antibodies. Now, suppose the body was not so well prepared; not so prompt in closing in upon the invaders. They then begin to multiply and when the body is roused a large number of bacteria are to be destroyed. A local process of inflammation and perhaps suppuration is the result. We may have a systemic infection. The process might have been nipped in the bud by vaccination or preparedness. Success attending vaccinal prophylaxis has carried it as a practice into the heart of the disease. There is a wholly different situation between vaccination during health, when only a few bacteria are to be checked, and vaccination during disease, when there are myriads of bacteria to be checked and disposed of, and the body largely robbed of its store of antibodies. The production of more antibodies by the tissues under the influence of vaccines leads to a sufficient reaction to effect a cure; where the capacity of the body for producing antibodies is low or exhausted, no cure can be hoped for. The effectiveness of vaccines applied in the course of acute febrile diseases must be accounted for by the principles of which experimental medicine has as yet no definite knowledge. The mutual relation between the tissues of the host and the parasite is complex and it behooves us, therefore, to be exceedingly careful in the use of vaccines.

The Therapeutic Use of Ascitic Fluid.—Timothy Leary and Robert H. Hastings offer this as a preliminary communication for the purpose of calling attention to the apparent therapeutic value of a substance hitherto discarded as valueless or toxic. The clinical results described are at least suggestive. It is their intention to carry out a wide series of observations on the value of ascitic fluid in nutritional disturbances, shock and infection. In the dozen cases reported the administration of the fluid has been followed by amazing results. The notes on these cases are brief, intended only to cover points of nutrition in feeble, poorly nourished babies.

New York Medical Journal, August 20, 1910.

A Critical Review of Existing Theories and the Presentation of a New Theory of the Etiology of Achylia Gastrica.—George Edward Barnes says that the purpose of his paper is to attempt to clarify our conception of achylia gastrica by presenting certain original observations. Achylia gastrica means gastric juicelessness and denotes the essential feature of the disease, making impossible the digestion of proteids in the stomach. He reviews some of the theories of achylia and infers that the so-called primary form of atrophy or achylia gastrica cannot be idiopathic, inherited, congenital, or the result from a congenital predisposition. He could therefore with reason question whether there is any such thing as a distinctive primary atrophy or achylia gastrica. From his further considerations he thought they were justified in inferring that the so-called nervous achylia gastrica has not been explained and even that its existence as a distinctive form has not been proved. He feels certain that the writers on this subject will admit that they have all been engaged in a guessing match and that they have found no real etiological basis for this disease and have made no scientific classification. In his work in stomach diseases he was much impressed by the observation that achylia gastrica without any usually well-known organic disease of the mucosa is so frequently accompanied by gastroptosis. It is significant not only that achylia is often associated with gastroptosis, but also that they occur at about the same age and most frequently in the female sex. He then considers how gastroptosis may cause achylia. The stretching of the nerves would seem to be a possible cause. If it is true, as suggested by his observations, that gastroptosis may cause lesions of continuity in the vagi which in turn cause achylia, we may infer that achylia in cases not associated with gastroptosis is probably caused by the same lesions. Any disease or injury which destroys the secretory axons, *e.g.* a severe neuritis or rupture from tension, would produce such lesions. It seems to him that his theory, which holds that achylia gastrica is caused by a lesion of the secretory axons of the vagus nerves, best explains all the chemical and microscopical conditions, and all the symptoms of the disease.

Blood Pressure and Uranalysis in Chronic Nephritis.—H. Brooker Mills says it is evident that but little work has been done with a view of establishing any relationship, directly or indirectly, between blood pressure and uranalysis, especially in the presence of albumin, tube casts, and the variable urea elimination occurring in chronic nephritis. He has made a number of comparative observations on healthy individuals, in whom the urea elimination was normal and the blood pressure practically so. Almost without exception a low urea elimination and a high blood pressure occurred in the diseased cases, while no such relation existed in the healthy. The objects in presenting this paper are: (1) To call attention to the frequency and importance of the relationship existing between urea elimination and blood pressure; (2) to urge the more frequent microscopical examination of the urine in the absence of albumin; (3) to make the urea estimation a regular procedure in uranalysis; (4) to urge the more universal employment of the blood pressure test in the diagnosis and treatment of disease, especially the various toxemias; (5) to stimulate comparative studies along the lines suggested, with the view and in the hope that, upon being able to determine the real value of the blood pressure test, both singly and relatively, we may thus secure an aid to the earlier diagnosis of conditions present than would be possible by the most careful physical examination and uranalysis.

Journal of the American Medical Association, August 20, 1910.

Ophthalmia Nodosa or Caterpillar-Hair Ophthalmia.—Walter R. Parker, after describing the symptoms of this affection, referring to the various theories advanced to explain them, and reviewing the anatomical changes which are by no means characteristic, reports the case of a man who consulted him in April, 1906, with a history of having had recurrent attacks of very severe pain and redness in the right eye at intervals of about 30 days since from October, 1905. After about three months of unsuccessful treatment it was discovered that just previous to his first attack he had worked to rid his trees of caterpillars. Examination showed five areas of infiltration in the superficial layers of the cornea, but did not reveal the presence of the hair. After an acute attack the writer determined to curette the indurated area. From the scrapings he recovered a hair which was classified as *Bombyx rubi*. In a short time the patient was cured. The author gives a table which contains a record of all the cases reported in the literature, 38 in number. In a majority of the cases there is a history of injury to the eye by a caterpillar; in the absence of such a history there is one of sudden onset of the symptoms, consisting of pain, more or less severe, much photophobia and lacrymation. These symptoms tend to subside, but do not entirely disappear, and exacerbations occur from time to time at intervals varying from four days to three years. The different tissues of the eye affected are the conjunctiva, cornea, iris, sclera, episclera, and choroid. There was a history of injury in 73 per cent. of the cases and the hair was demonstrated in 86.4 per cent. of the cases. The species of offending caterpillar was demonstrated in 50 per cent. of the cases in which the hair was found. The treatment was mainly symptomatic. Operative treatment has been limited to iridectomy and to the excision of nodules and hairs.

Primula Dermatitis.—O. H. Foerster states that the primula or primrose is frequently the cause of a dermatitis and that this fact is not sufficiently recognized in this country, as is shown by the few cases reported in comparison with the large number of cases reported and articles

appearing in English and German medical and botanical journals. The personal experiences of the writer comprises some forty or fifty cases, and he believes that a widespread knowledge of the toxic properties of the primrose will shed light on the etiology of many instances of so-called recurrent eczema and of cases of "mild erysipelas." This form of dermatitis presents itself in three types, depending on the degree of idiosyncrasy. First, those with an intense inflammation, erythematovesicular in character, at times with the formation of bullæ, and accompanied by more or less swelling. Others develop an erythematosquamous eruption of a less acute type, with considerable infiltration, after repeated attacks, and scaling continued over a long period. In others, there is an intense itching or burning sensation, confined to the pulps of the fingers, which are puffed, tense, and slightly reddened. The inflammatory reaction remains limited to those parts which come directly in contact with the plant. Repeated attacks do not develop immunity, but, on the contrary, seem to produce an increased susceptibility. The author believes that the source of the dermatitis must be sought for in the secretion of the plant, and thinks that florists should warn prospective purchasers of the danger of *Primula abconica* and *Primula sinensis*. The treatment is conducted according to the usual principles followed in cases of acute dermatitis.

University Medical Schools.—In his address to the graduates of the St. Louis University Medical and Dental Schools, James J. Walsh referred to the maimed and incomplete medical education of a generation ago in the United States, and to the present time movement that is reforming medical education. The one hope of medical education is, and always has been, organic connection with the university. The evolution of our medical schools has now reached this epoch. While this system is comparatively recent in this country, it is not new in the Spanish-American countries, where educational systems have been adopted from the mother Latin country, and as a consequence a good preliminary education has always been required. Dr. Walsh reviews the history of university schools from the establishment of the University of Alexandria to the present time, and points out the scientific work that the universities have done in medicine and surgery in ancient times and during the Middle Ages. The great universtiies founded during the thirteenth and fourteenth centuries did far more effective work than is generally recognized. Huxley said, in writing of medieval education, that the undergraduate work of the medieval universities was better than that of his time, and the postgraduate work was as fine as the undergraduate work. There is practically nothing in modern surgery that these men did not touch upon in their books. With the reorganization of the universities at the time of the renaissance the universities of Italy carried on original investigations of the greatest value. The history of science and medicine, as written, seems to contradict this. There is striking testimony to the papal patronage and encouragement in fostering medical education, and for seven centuries papal physicians have been the greatest contributors to medicine. The lesson that history teaches is that when medical education is seriously undertaken as a university department all is well; when it is not results are disastrous.

Permanent Elimination of Yellow Fever.—The achievements of Colonel Gorgas, the suggestions of Dr. Carter, and his own observations, have led J. F. White to state that yellow fever can be permanently eliminated. If the endemicity is once destroyed the chance of epidemic occurrence is also destroyed. Such work would require the cooperation of the Latin-American countries and Great Britain, and, perhaps, France and Holland. The plan may be summed up as follows: (1) Each center under one man's control and he given full power to make a steady, insistent, and minutely exact fight on all Stegomyia breeding places. (2) No attempt made to handle the sick, and so arouse the ire of the individuals. (3) Be most careful to make it plain that subordinates shall annoy no one, and see that they do not annoy. The officer should approach the question of human carriers only through friendly suggestion to local authorities. The achievement would be worth to the western world each year all of its cost.

A New Method of Inflating the Stomach.—Stewart Lewis has practised the following method in about 50 cases: He places the patient on the examining table, with the abdomen exposed, and arranges a siphon of carbonated water so that the patient can drink. He directs the patient to drink slowly at first, and then as rapidly as possible. The average patient takes about eight ounces, though in favorable cases half this amount will bring the outline of the stomach into view, while the mixture of gas and fluid gives to palpation a crackling feel and a typical splash apparent to the most inexperienced. The direct method of percussion is employed with a small wooden object such as a lead pencil or a paper knife. The following objects are attained: Size and position are accurately determined. With practice some idea of the gastric tone may be obtained. Roughly speaking, four ounces of fluid will lower the border of the normal stomach about an inch; in atony it may lower the border two or three inches. (3) Rapidity of escape of the gas into the intestines will be a crude test of the tone of the pylorus. Tumors may be more readily palpated. This method has the advantage over other methods of being safer and much less unpleasant, and, in the opinion of the author, it is efficient.

The Lancet, August 13, 1910.

An Aid to Diagnosis in Malignant Diseases.—Elsie M. Royle gives the results of the examination of the urine and a determination of the ratio of phosphates to uric acid in cases of malignant disease with the object of ascertaining if this ratio could be of use in diagnosing obscure cases of the latter. She summarizes her work as follows: From the results obtained and from the figures quoted it appears that an examination of the urine will prove of great value as an aid to diagnosis in obscure cases of cancer, especially in cancer of the alimentary canal and abdominal organs. In order to apply this test it is necessary to estimate the uric acid and phosphate content of the urine and to consider the figures separately, and then to take into account the ratio of phosphates to uric acid. The author considers that her figures establish the following facts: (1) That in cases of cancer the uric acid is usually higher than is found in healthy cases under similar conditions. (2) That the output of phosphates in the urine in the majority of cases of cancer decreased when compared with healthy individuals. (3) The ratio of phosphates to uric acid is almost invariably reduced in malignant disease below that found in health, any ratio below 4 being suggestive, especially if it remains low on several occasions, and any ratio below 3 is almost diagnostic of malignant disease or of a blood disease, unless further work shall prove that the same is found in other conditions. Before these conclusions can be definitely adopted it will be necessary to determine how far they are true of other forms of cachexia and what their relation may be to the secondary forms of anemia usually present in malignant disease.

On Occluding and Suboccluding Ligatures.—Victor Bonney calls attention to the fact that the application of a ligature in the course of a surgical operation produces in the tissue distal to it a condition of artificial infarction which, like that occurring spontaneously, may be either white or red, depending upon the method of ligature employed. From this point of view ligatures may be divided into two classes: Occluding ligatures, when every blood channel leading to the distal tissue is included in the ligature, and suboccluding, when a tract of tissue remains which is capable of establishing capillary anastomosis beyond the ligature and unincluded in it. The area of a white infarct dead of anemic necrobiosis and cut off from all vascular communication with surrounding tissues is singularly nonirritant to the structures in juxtaposition to it, provided no septic processes have been concerned with its production. On the other hand, a mass of tissue in a condition of red infarction is more or less dangerous as (1) a source of hemorrhage; (2) a powerful tissue irritant and an incentive to infection; and therefore (3) is a potent cause of adhesion. The logical conclusion is, therefore, that suboccluding ligatures should be avoided. The occluding ligature is quick, but in certain circumstances insecure, while the suboccluding ligature takes longer but is less liable to slip. This form of ligature and also the mattress suture can in most cases be converted into occluding ligatures by bringing the ligature back round the hemostatic forceps and tying it again on the opposite side. By this means the advantages of the encircling ligature with its perfect occlusion are combined with the security of the simple transfixion or mattress ligature.

The Effect of Radium on the Healthy Tissue Cells.—G. Percival Mills makes a perliminary report on some experimental work as to the effect of exposure to radium on the normal body cells. He used mice, making the application for 30 minutes in each case, and choosing the liver, as it is conveniently situated for application. The mice were killed at varying intervals after the exposure, and the liver examined microscopically. The earliest definite change noticed occurred about one hour after irradiation. Three hours after irradiation the liver cells were profoundly altered. The protoplasm was deeply granular,

and the nucleus stained very clearly and was considerably swollen. The whole cell was slightly increased in size. The areas of mixed cell infiltration round the veins were larger and more numerous, and consisted mainly of lymphocytes and spindle cells, but there were occasionally polymorphonuclear leucocytes. There was a general increase of connective tissue cells throughout the section. The hyperemia was intense. Sections taken after six hours showed that the liver cells had become more normal. After 24 hours the majority of the liver cells appeared normal. In most of the sections there was a place near the edge where the cells suffered a greater and more permanent change; this seemed to correspond to a spot immediately over which the radium was applied. Neglecting this area of intense action, the liver may be said to have become normal in three days after irradiation. There was a late inflammatory reaction coming on about the fourteenth day and lasting much longer than the primary reaction.

British Medical Journal, August 13, 1910.

Tetanus in a Septuagenarian: Recovery.—E. Barnes reports the case of a man, 75 years old, who developed tetanus following an injury to his forefinger. The tetanus was very severe; only a few drops of fluid nourishment were got down his throat at a time. Rectal feeding was resorted to. During his attack he developed a severe bronchopneumonia with edema of the leg. These complications gradually subsided and about two months after the accident he was feeling well, except for slight stiffness and cramps in one leg and both arms. Medication consisted of 50 cubic centimeters Pasteur's dried serum at first, followed by 20 cubic centimeters of the same daily for a week, then by 20 cubic centimeters daily of Allen and Hanbury's serum for nine days, injected under the abdominal skin. Chloral was given in 20-grain doses thrice daily. He also received as much precipitated sulphur, in treacle, as could be got down; he took half a pound in all. Very moderate purgation resulted. The recovery seemed remarkable, considering the patient's age, the severity of the disease, and the complications. He was inclined to give some credit to the sulphur.

Intestinal Myiasis.—Stephen M. Laurence reports the case of a child of thirteen months with this infection of about eight months' duration, and in whom it was difficult to image frequent reinfections. When the child was four or five months old the mother found maggots on his napkin. Since that he has passed maggots up to the day he saw him. They were passed intermittently, the longest interval being a month, and a week the longest period of continuous passing. Although seen and treated by more than one doctor, he has never been cured, and now, eight or nine months after their first appearance, he still passes them.

Sloughing of Lung Tissue in Pyopneumothorax.—Sidney W. Curl reports the case of a girl, sixteen years old, with pulmonary tuberculosis in which a pneumothorax occurred, and at the post-mortem examination of which several sloughs of lung tissue were found in the pleural cavity. He was under the impression that the case was a unique one; but he finds that Coats, in speaking of the formation of cavities in phthisis, says: "By the separation of the sloughs the cavity of the abscess may come to communicate wtih the pleural cavity, and so pneumothorax may result. Sometimes there is even a gangrenous condition developed, and actual sloughing of pieces of lung tissue occurs." With this exception he is unable to find any reference to the subject in the literature.

Berliner klinische Wochenschrift, August 1, 1910.

Operative Treatment of Spastic Paralysis by Resection of the Posterior Spinal Roots.—Foerster sums up our knowledge of this resource to date, adding the references to the literature, as far as he is aware of them. He evidently is ignorant of the recent work done in this field in the United States. Thus far the European material has been reported by Foerster (including the articles published by Küttner and Tietze, who have done his operations); Gottstein, Kotzenburg, Anchütz, and Hevesi. The last three mentioned have operated in but a single case each. Gottstein has operated five times, but in some of these, at least, the operation was for the gastric crises of tabes in which life was menaced. The operation, therefore, is still largely in the personal or individual stage. We do not learn the number of Foerster's cases from this article. Küttner has operated for him at least ten times, while his colleague, Tietze, who was the first to carry out Foerster's ideas, must have operated on a number of occasions. The intervention is a severe one, and questions will arise as to whether one should operate in one or two stages, and whether or not bilateral resection is indicated in a given case. At present Foerster concedes that his operation is not a specific for spastic paraplegia, but must be conjoined with all other useful measures, such as tendon and nerve transplantation. On the other hand, it is indispensable in all severe cases. If we read between the lines it seems evident that this article is not so much concerned with what the operation might accomplish under favorable circumstances as with the means of minimizing the dangers of a formidable surgical intervention.

Therapeutics of Gonococcus Vaccine.—Schindler appears to devote himself chiefly to the validity of the claims of rival manufacturers of gonococcus vaccine, which to a certain extent are based on different viewpoints. Leaving this question of relative superiority aside, he has obtained the best general results from vaccinotherapy in epididymitis and diseases of the adnexa, together with gonorrheal arthritis. Failures must be expected at times, and coincide chiefly with the presence of mixed infection. This necessitates a guarded prognosis, for it is in precisely these affections (annexitis, epididymitis, arthritis) that we are most likely to encounter mixed infection.

Superinfection in Rabbit Syphilis.—Tomaszczewski in using the term superinfection refers naturally to the successful inoculation of a disease already prevalent in the individual. Superinfection of syphilis in mankind is a somewhat doubtful phenomenon. A second successful inoculation must either take place before the first is in full evidence or after a certain period in which the community is lost. It seems to be quite otherwise in rabbit syphilis; for an animal with syphilitic keratitis remains susceptible to scrotal inoculation, while conversely animals with scrotal primary infections are still susceptible for months to intraocular inoculation. The author does not attempt to explain these phenomena.

Gasis's Method of Staining Tubercle Bacilli.—This method, devised last year in Prof. Senator's laboratory, is said by Gasis to be more delicate and trustworthy than any other in vogue, although some regard it as too complex for routine use. This alkali test, while possibly susceptible of simplification, is certainly not less complicated than its competitive procedures. The sole drawback to Gasis's method lies in the necessity of preparing the color solution fresh for each test (4 or 5 c.c. of a solution of 1 gm. eosin in 5 c.c. alcohol and 95 c.c. water must be boiled in a test tube with crystallized mercuric chloride). Tubercle bacilli, thus stained, are alkali-fast. Not all of Koch's bacilli are acid-fast, and tests based upon that theory are therefore fallacious. As smegma bacilli are also acid-fast, they may readily be excluded, as may naturally all other unknown acid-fast organisms. No one to-day would confine himself to a single test, however satisfactory; and Gasis only claims that his method should be used in conjunction with other well-known procedures, not only for corroboration of the results but also for checking up in doubtful cases.

Sources of Fallacy in the Antiformin Method.—Beitzke refers simply to the danger of the introduction of alien organisms from without which may behave like tubercle bacilli in the sediment used in the antiformin method. Acid-fast bacilli may be found at times in the scrapings from faucets, rubber tubes, etc.; and in fact in any apparatus or solution used in making tests; this even if the utmost cleanliness is employed. Whether these represent tubercle bacilli or only simulate them they are equally sources of fallacy. Of much greater significance is the discovery of bacilli closely resembling Koch's in sections from normal tissues. These were clearly artefacts from impure water or apparatus. To avoid all such sources of fallacy, the latter should be tested independently for the presence of acid-fast bacilli. Even distilled water cannot be trusted as to purity. Mere attempts at strict asepsis are insufficient, the author maintains, unless such parallel or control tests are made use of.

Transfusion of Blood in Man Under the Use of Control Tests.—Schultz concludes a serial article on this subject as follows: Defibrinated human blood which had dissolved and agglutinated blood corpuscles in vitro caused, when injected into the circulation of a patient with secondary anemia, acute collapse, chills, and fever to 40° C., and edema. Nevertheless, although the patient failed to obtain any new erythrocytes, he was benefited by the operation. In the main, however, cases of transfusion after operation did well when the blood and serum injected reacted negatively in vitro as to the presence of isoagglutinins and hemolysins. The author believes that such biological control tests should always be made before transfusion.

Münchener medizinische Wochenschrift, July 26 and August 2, 1910.

The Ehrlich-Hata Remedy in Nonsyphilitic Affections.—Loeb mentions incidentally that in the course of treating syphilitics with the new Ehrlich-Hata preparation and when the latter is tested independently on nonsyphilitic affections, a collateral field of usefulness seems to be suggested. It has already given phenomenal results in spirilloses, for which it may turn out to be a specific. The author saw a confirmed case of ordinary juvenile warts of the hands and face disappear rapidly under its use. The dermatosis known as lichen simplex Vidal has also yielded to it. Other writers have noted the accidental disappearance of psoriasis. These facts are not in themselves singular, for arsenic is believed to have power over such affections.

Epidemic Cerebrospinal Meningitis with Especial Reference to Carriers.—Mayer and three others have made a study of recent epidemics of this affection, in which naturally the questions of transmission, disinfection, carriers, etc., received due attention. Over 9,000 soldiers in barracks were examined in a research for latent carriers, and less than 2 per cent. in average found to harbor the meningococcus. No connection between carriers and epidemics was found. The regiment with the largest percent. (2.4%) had never had a case of the disease, let alone an epidemic. The percentages above given refer to a single examination. A much smaller series, subjected to repeated examinations, gave only a slightly higher per cent., and it is safe to say that 2 per cent. of all healthy individuals harbor the meningococcus in the throat, and this without any regard to the presence of epidemics or sporadic cases. Accumulation of troops in barracks does not appear to increase the number of carriers. In fact all attempts to penetrate into the mystery of this disease and control its spread, as is practicable with typhoid fever and cholera, have been attended with failure.

Wassermann's Method in Differentiating Cerebrospinal Syphilis from Multiple Sclerosis.—Hauptmann and Hössli, working under Professor Much, have reached the conclusion that the numerous negative results with this reaction in testing the cerebrospinal fluid in cerebrospinal syphilitics are due to the fact that the amount of liquor used in the test contains too few inhibitory bodies (by 0.2 c.cm.). When this is offset by adding more liquor positive reactions are much more frequently encountered. It also becomes possible to differentiate between cerebrospinal syphilis and multiple sclerosis.

Treatment of Anthrax.—Koelsch states that the old-time active surgical therapy has not accomplished much, and that better results are obtainable by medical measures, such as rest, dietetics, and cardiac stimulants, including alcoholics. In very high degrees of inflammation the carbuncle should be opened by cross-incisions, while the thermocautery should be employed in the periphery, to arrest the spread of the process. Pure tincture of iodine may also be injected peripherically, one or two drops at a distance of 5 to 10 cubic centimeters circularly about the pustule. Measures like these are employed whenever the peripheral inflammation takes on an erysipelatous character, which latter gives the indication for abortive treatment. Barlach of Neuminster, who sees many such cases, has pursued this plan with success for many years. Serotherapy has been employed in these cases for some years in Italy, with alleged reduction of mortality and improvement in cosmetic results. This resource has also been tested in Bavaria of late years, the serum having been thrown into the veins. The benefit has been of a startling character (the serum is prepared by a well-known commercial house). With serotherapy only the most conservative local measures have been employed.

Treatment of Variola.—Drever, who is attached to the Board of Health in Cairo, Egypt, has come into constant contact with variola cases, which are in evidence every winter and spring. The light treatment answered as far as it went, but such measures cannot prevent the decomposition of pus. The author has used potassium permanganate in saturated solution, and believes it accomplishes all the good that can be effected by the Finsen light, besides being a perfect deodorant. Naturally it is very difficult to learn whether this treatment has any real effect on the course of the disease or the mortality. It certainly influences favorably the secondary suppurative fever, and in this connection the cosmetic results.

Ascaridiasis and Its Treatment with Oleum Chenopodii.—Gockel calls attention to the efficiency of this old American remedy in roundworm disease. It is well known that ascaridiasis may simulate a great variety of severe diseases, and that it is often necessary to exclude it before making a diagnosis. Once this capacity for simulation is admitted the need of a roundworm destroyer is magnified, not only for diagnostic but for therapeutic ends. Hence, perhaps, the rediscovery by German pharmacologists of the old American remedy, which is admitted to have fallen into unmerited disuse. The technique advised by the author is complicated. The stomach should be empty for two days before the remedy is given. The dose of the latter should vary with the age of the patient. The author gives quantities for adults only, children's doses, presumably, to be calculated by weight and age. An adult takes two or three drops every three or four hours, in combination with menthol and in association with ordinary laxatives, such as castor oil.

Deutsche medizinische Wochenschrift, August 4, 1910.

Temporary Cortical Blindness from Commotio Cerebri.—Hirsch relates two cases of which the first was an example of total blindness following blunt violence on the occiput. It set in immediately after the injury and lasted two and one-half hours as total blindness. It then passed into homonymous hemianopsia of the right side. This condition had passed away by the third day. The case appears to be unique. Those which most closely resemble it in the literature appear to have been due to hematoma of both optic nerves, which in the present case could clearly be excluded. The hypothesis of a single large hematoma compressing the cortical visual centers may also be excluded forthwith. In hematoma of the optic nerves, from four days to six weeks seems to have been required for absorption of the clot and restoration of vision. It must be borne in mind, however, that this explanation of the cases in point is largely conjectural. A few cases of homonymous hemianopsia alone, succeeding upon occipital traumatism, are also known. The author's second case was of this type. It persisted for nine months, and was believed at first to be due to hematoma pressing on the occipital lobes. A study of the symptoms of hematoma of the dura did not reveal ocular symptoms of the character above described; and from a careful analysis of the symptoms of violence in this part of the body, the author concludes that the condition known as commotio cerebri is the one best adapted to explain the occurrence of these transitory eye disturbances.

The Present State of Our Knowledge of the Viscosity of the Blood.—Krone concludes, after comparing the various data as to the clinical significance of the changed viscosity of the blood, that our attitude must continue to be one of reserve. Workers have tested all kinds of blood (arterial, venous, mixed, etc.), with all kinds of methods. What is most needed in future is systematic, practical, bedside research. Purely theoretic and experimental treatment of the subject does not lead to practical conclusions. In other words, the viscosimeter, as used today, is of no practical benefit to the physician; for determinations of viscosity as thus secured have no practical significance.

Amenorrhea and Tertiary Syphilis.—Meirowsky and Frankenstein claim to have isolated a special syndrome, hitherto undescribed, in connection with severe and extensive tertiary syphilis. Three cases are sketched. Each woman suffered from severe tertiary syphilis. Each one, sexually mature and active, had had pronounced amenorrhea, lasting from six to eight years. Under antiluetic treatment two recovered their menses, while the third developed hemorrhages which pointed to vicarious menstruation. The evidence seems conclusive that the association of severe tertiary syphilis and protracted amenorrhea is not an accident. The question of specific oöphoritis naturally suggests itself as a ready explanation, but this seems sidetracked by the occurrence of ovulation and menstruation in patients with syphilitic ovaries. It is evident that the spirochete, if it does not attack the ovaries in situ may at least attack the blood, and so establish an anemia with resulting amenorrhea. In such a condition, return of menstruation should coincide with recovery of the normal blood count. It is evident that the deposit of the spirochete in the ovary is responsible for syphilitic sterility, syphilis of the fetus, syphilitic abortion, and congenital syphilis in general. Such an association of cause and effect is common enough. But the problem of explaining this very rare case of protracted amenorrhea is much more difficult. The women all suffered from very severe destructive lesions of the skin and periosteum. One developed parasyphilis (tabes dorsalis). The ovaries were not palpated in any case and there were no evidence of adnexitis. Such cases necessarily remain paradoxal.

Book Reviews.

Die Spinale Kinderlähmung. Eine klinische und epidemiologische Studie. Von Professor Dr. Eduard Müller, Direktor der medizinischen Universitats-Poliklinik in Marburg. Mit Unterstutzung von Dr. med. M. Winkmüller, Assistenzärztin der Poliklinik. Mit 21 Textabbildungen und 2 Tafeln. Berlin: Verlag von Julius Springer, 1910.

Great interest has been manifested by the profession in recent years in anterior poliomyelitis, especially since our last big epidemic. This is one of the best contributions on the subject which we have seen. Interesting illustrative cases are introduced throughout the book. After a brief chapter on experimental poliomyelitis in apes, the pathological anatomy and pathogenesis of the disease are described, and this is followed by an excellent chapter on its epidemiology. The main part of the book is devoted to symptomatology; but there are also chapters on the cerebral type, on abortive cases, and on its early diagnosis and treatment.

Kurzgefasstes Lehrbuch der Kinderheilkunde für Ärtzte und Studierende, von Dr. Carl Seitz, A.O. Universitätsprofessor und Vorstand der Kinderpoliklinik am Reisingerianum in München. Dritte vermehrte und völlig umgearbeitete Auflage. Berlin: Verlag von S. Karger, 1910.

The publication of the third edition of this work, the first edition of which made its appearance seventeen years ago, has been necessitated by the advances in the pediatric science during the past ten years, especially in the knowledge of biology in medicine, in the action of internal secretion. The book has been completely rewritten and at present appears as a volume of 550 pages, which gives in brief form the chief facts needed by the practitioner, at the same time as briefly as possible taking up the physiology and pathology of disease. The work is much shorter than most of the modern German works upon the subject, as the author devotes but little time to the discussion of abstract theory. The facts as known, however, are given in a clear, concise, and readable form, and the book appears to be well brought up to date. The book reminds one more of some of the modern American works on the subject, in which the practical outweighs the theoretical. For the American student who reads German as well as English this book will prove a useful textbook. For the student to whom the reading of German is a labor, his time might be expended to better advantage in the perusal of an English or American book, as the book is not sufficiently superior to our own upon the subject to make the extra labor profitable. The book is not illustrated.

Die Epilepsie im Kindesalter, mit besonderer Berücksichtigung erzieherischer, unterrichtlicher und forensischer Fragen dargestellt. Von Prof. Dr. med. Heinrich Vogt, Nervenarzt und Abteilungsvorstand am neurol. Institut in Frankfurt a/M. Berlin: Verlag von S. Karger, 1910.

Everything points to the desirability of a book on this subject. Epilepsy as a so-called idiopathic disease seldom develops after the age of twenty-one. Attacks begin most commonly in youth. Fits may follow an injury to the cortex sustained at birth or be due to a cortical vascular disturbance during infancy. Early convulsions predispose to epilepsy later in life. All sorts of peripheral irritations serve to disturb the balance in children with faulty cortical nerve cells. The author treats the subject in an excellent manner, both from the standpoint of neuropathology and that of psychopathology. The book comprises 225 pages. There are five chapters: on etiology, symptomatology, pathological anatomy, diagnosis, prognosis, treatment, and prophylaxis of epilepsy in childhood and youth; and a chapter on the social status of the youthful epileptic in the community and his relationship to criminology. The book is interesting, and seems authoritative. It contains a bibliography chiefly of German authorities.

The Johns Hopkins Hospital Reports. Vol. XV. Baltimore: The Johns Hopkins Press, 1910.

With three exceptions the fifteen monographs which comprise this volume of over 500 pages are devoted to the subject of pneumonia, the experiences of the Johns Hopkins Hospital for the past twenty years with this disease being collected by various authors. Four of the articles are by Chatard. This writer makes an analytical study of the 658 cases of pneumonia which have been admitted to the wards since 1889, an analysis of the leucocyte counts in 582 cases, a study of terminal pneumonia based upon thirty-five cases, and a review of thirty-five cases of acute pericarditis complicating the disease. Fabyan analyzes the pathological reports of 195 cases. Emerson reports on the mode of termination in recovery cases, including temperature fall, leucocyte count, chloride output, and resolution of physical signs. Marshall writes on acute endocarditis complicating pneumonia. McCrae offers contributions on the subject of empyema and delayed resolution. Steiner reports three cases of venous thrombosis in pneumonia, and reviews the literature upon this subject. Howard discusses pneumococcic arthritis, and Hanes pneumococcic meningitis. The series, taken together, makes up a most valuable study of the clinical aspects of pneumonia and its complications. The other three articles included in the volume are a bacteriological and clinical study of seventy-four cases of diarrhea in children by Knox, a study of skin transplantation by Davis, and a review of the experiences of the hospital with epidemic cerebrospinal meningitis and the Flexner-Jobling serum, by Sladen.

Medical Electricity and Rontgen Rays. By Sinclair Tousey, A.M., M.D.; Consulting Surgeon to St. Bartholomew's Clinic, New York City. Philadelphia and London: W. B. Saunders Company, 1910.

This book is the most ambitious work on electricity and its medical aspects which has appeared in recent years. A great part of the book is devoted to the physics of electricity in general, and careful descriptions and explanations of the various forms of machines which produce or transform the currents abound. In this part of the work the author does not confine himself strictly to his subject, wandering occasionally into such bypaths as wireless telegraphy. Such digressions, however, do not in any way detract from the value of the work. The physiology of electricity receives careful attention, and a short chapter is devoted to electropathology, including lightning stroke. Electrodiagnosis is covered in the usual manner by reference to excellent photographs showing the motor points. Possibly slightly more emphasis is laid upon the relative strength of the contractions at the different poles than is usual in such works, this rather abstruse subject being treated in a very clear manner. Under electrotherapeutics ionic medication by electrolysis, static electricity, and the high frequency current are treated especially fully and rationally. The book is conspicuous among works upon this subject in being entirely devoid of extravagant exaggeration as to the curative powers of the various currents and by the care with which the author goes into details as to strength of current and length of treatment indicated for the various conditions. Brief chapters are devoted to phototherapy and to radium, and over 400 pages are given up to the *x*-ray. The book is complete, thorough, and scholarly, and will probably be accepted as the authority in the English language on the subject of electrotherapy. It is well printed and bound, and is profusely illustrated with photographs and diagrams.

Chirurgische Operationslehre für Studierende und Aerzte. Von Prof. Dr. Friedrich Pels-Leusden, Oberarzt der chirurgischen Universitatsklinik und Leiter der chirurgischen Universitätspoliklinik an der königlichen Charité zu Berlin. Mit 668 Abbildungen. Berlin und Wien: Urban & Schwarzenberg, 1910.

The author, disclaiming any ambition to write a complete "Operative Surgery," sets forth in a very readable volume of about 700 pages the material he has used for lectures and practical courses in his official work. It is essentially a practical book, and, without sacrificing clearness to brevity, seems to cover a great deal of ground in a very concise manner. The illustrations are excellent and very enlightening. The use of shading in those of resections, amputations, etc., to show the portion to be removed and that to be left behind is especially commendable, though the failure to label the illustrations, common in German books, puts the reader to unnecessary trouble. Another fault, also common among German writers, is the apparently absolute ignorance of all that is not German. This is the most charitable interpretation to be put upon behavior that has often been called by a harsher name. With the exception of a few Englishmen and Americans, long since passed to the "Great Beyond," modern surgery has evidently been built up almost entirely by subjects of His Imperial Majesty. Either Dr. Pels-Leusden is trying to "stem the tide" or else he is behind the times, for he still snips off the tops of his tonsils, and does not even mention the modern operation of tonsillectomy. He clings to the old idea of the importance of a complete dissection of the synovia in his resections of tuberculous knees. Possibly if his book goes through the editions to which it really seems entitled, its author may glean from the works of other Germans something of what is going on in the outside medical world.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Thirty-Second Annual Congress held at Washington, D. C., May 3, 4 and 5, 1910.

(Special Report to the MEDICAL RECORD.)

JAMES E. LOGAN, M.D., OF KANSAS CITY, MO., PRESIDENT

(*Concluded from page 343.*)

Second Day, Wednesday, May 4.

Intranasal Route for Growths of the Hypophysis Without External Incision with Report of a Case of Intranasal Decompression.— Dr. NORVAL H. PIERCE of Chicago presented a preliminary report of a case of this nature. The patient suffered from diplopia, increasing blindness and headache and it was suspected that he might have a growth in the sphenoidal sinus. There was a mucopurulent discharge coming over the portion of the middle turbinate left from a previous operation; removal of this and of the anterior wall of the sphenoidal sinus was followed by exploration of the ethmoidal region in which nothing was found. The removal of pressure thereby occasiontd led to an improvement in the pain lasting only two weeks. A second operation was done later consisting of the following steps (1) local anesthesia with adrenalin, (2) removal of at least both middle turbinates (3) removal of the septum between the following lines, (a) a vertical line drawn downward to the floor of the nose to the glabella; (b) a horizontal line drawn downward and backward from the lower anterior margins of the nasal bones to the body of the sphenoid bone; (c) a diagonal line which intercepted the lower extremity of the line (a) and ended at the point where the vomer joined the sphenoid. Flaps from the mucosa might be preserved to cover the cut edge of the septum. This was best removed by cutting forceps and chisel. (4) Removal of anterior walls of both sphenoid cavities and removal of the dividing septum. This was done either by means of the punches already employed for this work or by means of specially constructed chisels. (5) Packing the nasal cavity with xeroform gauze. After healing was well under way we might proceed with the second step. (1) Anesthesia, local or general with adrenalin. (2) Removal of inner wall of sphenoid and exploratory puncture of walls of tumor. If it is cystic, then drain; if solid, remove with curette.

Dr. J. N. MACKENZIE of Baltimore called attention to the fact that one of his assistants at the Johns Hopkins, Dr. West, had already performed the intranasal operation several times on cadavers and had published his views in the *Journal of the American Medical Association.*

Dr. R. C. NYLES of New York had had three cases in which the tumor involved the sphenoid sinus and in which it was necessary to remove the septum. Two were done by removing the nasal bone to one side, breaking loose from the frontal sinus and throat back to the sphenoid. The sinus was easily entered and the growth removed. The hypopoysis was easily seen and could be entered.

Diagnosis of Dentigerous Gysts of the Antrum.— Dr. PIERCE also presented this paper, saying that for many years the division of these growths into follicular and periosteal had obtained. The former had its origin in errors or disturbances of development through which degeneration of the dental sac eventuated and was clinically characterized by the fact that the tooth to which the sac belonged was missing in dentition unless it was a supernumerary tooth. This variety was extremely rare. The other variety originated from a peridontitis at the apex of the root of a fully developed tooth. Microorganism gained access to the peridont from the diseased pulp through the root canal. Eliphelial remnants participated in the process and the end result was a small cyst perched on the apex of the root which was not infrequently removed in situ at the time of extraction. The sac consisted of connective tissue lined with epithelium. The cyst contents varied according to the presence or absence of infection. The cyst might increase in size until it perforated the antral wall. Two illustrative clinical histories were given.

Case Reports Illustrating Ocular Affections Due to Intranasal and Accessory Sinus Disease.—Dr. LEWIS A. COFFIN of New York City read a paper with this title and presented a series of *x*-ray plates, together with a collection of charts illustrating the variations of the visual field for white and for colors. Cases were often not recognized in which aid was sought for relief to eye symptoms but in which the lesions involved the nasal mucosa and sinuses. He reported four such cases from his own experience and collated the literature on the subject. The various conditions of the eyes in such cases were summarized as follows: Circulatory disturbances, venous engorgement, choked disc, hyperemia, edges of disc blurred, pallor of disc and frequent concentric contraction of the visual fields, especially the red. The reader of the paper exhibited charts of radiographic pictures of eight cases. He said that there were probably physiological variations in the normal fields of vision and that they varied under varying conditions as fatigue, light, etc. No definite conclusions were drawn by the author as his report was simply one of progress, but he was inclined to believe that further experience in studying the visual fields of these patients would be of great assistance in diagnosis. The removal of enlarged turbinates pressing on the septum would of course cause eye symtoms and relief of this pressure would cause them to disappear.

Dr. F. J. PARHER of New York City had examined the eyes of the cases mentioned by Dr. Coffin. He said the eye men met a certain class of cases with optic atrophy and that if no apparent cause could be found it was customary to give them the iodide. He believed that many of these cases which had not improved and had been injured by the remedy were due to ethmoidal and sphenoidal disease. Some of Dr. Coffin's cases did not had sinusitis but intranasal turbinate swelling, and could be divided into two classes, those due to circulatory disturbances and those due to perineuritis, causing swelling and beginning atrophy. These cases showed first in the visual fields. The object of the paper was to find the value in diagnosis of these disturbance.

Dr. C. G. COAKLEY of New York said that in three of his recent sinus cases there had been no contraction of the visual field. In another case with unilateral involvement both eyes were practically normal. The matter, was, however, well worthy of further investigation.

Rr. H. L. SWAIN of New Haven said that, considering the relations of the optic nerve to the walls of the sphenoid, it was surprising that it was not not always affected in lesions of this cavity.

Dr. GREENFIELD SLUDER of St. Louis had seen a case of a boy who had had a headache and suddenly gone blind. The gap between the middle and superior turbinates was red and edematous. With great difficulty he had gotten this area shrunk with adrenalin, and the next morning, after a gush of a teaspoonful of pus and blood from the mouth, the boy could see.

Transportation of Rib Cartilage Into the Nose in a Case of Nasal Deformity.—Dr. D. CROSBY GREENE, Jr. of Boston presented this paper. The patient was a young man referred to him on account of a deformity of the nose received in a football accident eight years ago. He had had an abscess of the septum following the injury. There was a symmetrical flattening of the organ at the bridge. Under ether the space for the implantation of

the rib was prepared while at the same time the latter was carefully dissected away from its muscles, having been exposed by an oblique incision over the eighth and ninth ribs and removed without any injury to its perichondrium. In the meantime a vertical incision was made through the septal mucosa of the left naris just posterior to the mucocutaneous junction. Through this incision two layers of membranous septum were separated by knife dissection anteriorly as well as posteriorly. At its upper and posterior portions the chamber thus formed was enlarged backward and upward over the depressed nasal bones by means of a sharp rasp, which elevated the skin and soft tissue from the nasal bones. The size and shape of cartilage to be used were determined by fitting a piece of sterilized leather in the space prepared. A piece of cartilage was then fashioned according to this pattern and inserted into its new position, the wound closed by a single catgut suture, and both nares lightly packed with gauze. Healing was by first intention, and there was only moderate swelling of the nose following operation. The rib wound really caused more discomfort than the nose wound. A hematoma formed in the gap left by the removed rib and delayed union at this site, but in two weeks the man was all right.

Syphilitic Stenosis of the Oropharynx.—Dr. J. M. Ingersoll of Cleveland reported this case. The patient was a young man who had acquired his initial lesion two years before. There was difficulty in swallowing fluids, which regurgitated through the nose. Solids could not be swallowed at all. There was a nasal opening through the scar tissue about 1 cm. in diameter. Just below the level of the tongue scar tissue could be seen extending across the oropharynx, uniting the lateral and posterior walls of the oropharynx with the tongue. In about the center of this tissue there was an opening ½ cm. in diameter, through which food and inspired air could pass. The breathing was labored, and the patient weak and emaciated. A free incision was made to the lateral pharyngeal wall on each side and then a good view of the larynx could be obtained. All structures below the level of incision were apparently normal. In about a month of comfort the cicatrization began to reappear and the man was again incised and given a rubber bougie to pass several times daily. He then was lost sight of for five months, during which time he had failed to use the bougie, and fresh incisions were called for. He was then given metal tubes to use so that the tissue might not recontract. Dr. Ingersoll related several similar cases collected from literature referring to the method of treatment of the late J. E. H. Nichols, reported to the association in 1896.

Dr. J. H. Bryan of Washington commented on the obstinacy of these cases, and had found all plans unsatisfactory. He had tried the flap operation, bringing the upper and lower edges together and trying to form a posterior pharyngeal wall, yet there had been contraction, and his patient was very uncomfortable.

Observations of the Variety of Germs Present in Wounds Following Operations on the Faucial Tonsils.—Dr. Alexander N. MacCoy of Philadelphia reported the results of his own observations. Some 20 cases were examined. Of these, 9 showed mostly staphylococci and streptococci. One showed the predominating organisim to be a short, stout, spore-bearing bacillus. In another it was a short, stout, unidentified bacillus, singly and in pairs. In 9 of the cultures there was no predominating organism, but colonies of cocci and common mouth bacilli. In 4 of them, however, a large diplococcus was found, and in 2, irregularly beaded bacilli. In 1 culture there were proteolytic colonies which digested the blood serum; in none of the cultures were the Klebs-Loeffler bacilli found. The author concluded that there was no predominating organism in the pseudomembranes; that mouth bacteria were to be found in all cases, in varying quantities, the cocci being the most numerous, and that cultures would most often show staphylococci and streptococci, due probably in part to their greater hardiness on artificial media.

Lymphosarcoma of the Nasopharynx and Tonsils with Results of Operative and Medicinal Treatment.—Dr. Clement F. Theisen of Albany, N. Y., reported three cases. Two more cases had come under his observation during the past winter but were not included in the report. Case 1 was a boy of 14 years, operated on under general anesthesia and then placed on arsenic carried to the point of tolerance. Coley's serum was not used, as the author's experience with this remedy had been unfavorable. Temporary benefit resulted but the boy had recently died. Case 2 was a man of 48 years. The mass was removed from the left tonsil under cocaine and adrenalin, but recurred in the larynx, the original site remaining free from deposit. Arsenic seemed to keep the laryngeal recurrence stationary and the man is now comfortable. Case 3 was a man of 32 years, with a growth apparently confined to the right tonsil, and was removed by dissection of the right tonsil entire. The wound healed well but it was too soon to predict the eventual outcome. Arsenic has apparently had a good effect. No attempt was made to cover the literature of the subject in the author's paper.

Vaccine Therapy.—This subject was discussed in joint session with the American Otological Society and the American Climatological Society. Papers were read by Dr. H. S. Birkett, C. G. Coakley, and F. C. Cobb, representing the Laryngological Association.

Dr. Birkett presented the following conclusions: (1) Vaccine treatment will sterilize the accessory sinuses of the nose when the subject of chronic disease. (2) The chronic discharge of mucus from the accessory sinuses is due not so much to bacterial infection as to habit-secretion. (3) The symptoms are due not to infection but to hypersecretion and retention. (4) Although vaccine therapy is a valuable adjunct to treatment, the establishment of free drainage by the removal of polypoid masses and redundant mucosa is more important. (5) The cases of sinusitis showing a tendency to become chronic should be treated carefully by homologous vaccines.

Dr. Coakley took a less hopeful view of vaccine therapy. His results had led him to the following conclusions: The bacterial flora of the sinuses consisted of the following organisms: streptococcus pyogenes, micrococcus albus and aureus, staphylococcus pyogenes albus and aureus, and bacillus mucosus capsulatus. The opsonic index has been unsuitable either as a means of clinical diagnosis or as a criterion for further treatment. The vaccinations made in varying strength have not been followed by the changes in the opsonic index which would be expected, were this method of treatment one on which we could rely in practical work. The amount of time necessary to carry out fully "a careful opsonic treatment was not only beyond that which the ordinary practitioner could afford to spend, but was with the present technique and status of the subject quite out of proportion to the value of the information which one might derive from such a procedure. The therapeutic results of his own cases were, in his own judgment, absolutely valueless. He could not see, on the other hand, that any harm had been done to his patients. Before the use of vaccines the chronic cases had had frequently periods of improvement of the symptoms and periods of aggravation. In a few instances some improvement was noted after the first or second injection, but later the discharge and other symptoms returned as they had done under other plans of treatment.

Dr. Cobb had had good results in clearing up chronic ear discharges, but not such good results in nasal cases, although the anatomical conditions so far as closed cavi-

ties draining through narrow openings were concerned were apparently alike. In a series of atrophic rhinitis cases, however, the results were better. A bacillus of which he could find no description was found in pure culture in all cases. From it a vaccine was prepared and injections varying in amount from 150 million to 500 million were made. A very general improvement in odor, amount of crusts and discharge had resulted, yet in no instance could an absolute cure be claimed. Before commencing vaccine treatment these patients were in the habit of using nasal washes, and this treatment was not changed while carrying out the injections except that before periodical examinations they were not allowed to use a douche for twelve hours. The patients themselves were enthusiastic over the results of treatment. Autogenous vaccines seemed to yield better results than stock vaccines. The same general degree of results had followed in sinus cases—improvement, but no absolute cure.

Dr. J. Solis-Cohen of Philadelphia had given thirty years ago the first injection of tuberculin ever made in Philadelphia. In one case he had succeeded in curing a man in whom not only injections of tuberculin were made, but the remedy was rubbed into the laryngeal ulcerations, and rectal injections were taken every night. He had always used the old tuberculin of Koch when he could get it. When he began the practice of medicine half a century ago it was customary to apply fly blisters over the site of pulmonary lesions. We knew nothing of the bacillus at that time. Many of the cases improved, and since serum treatment and tuberculin had come into use he had wondered if the absorption of some of the serum raised by these blisters was not the real cause of the improvement. Acting on that principle, it had been his custom for a long time to blister the chest below the clavicle, taking care that the blister should not burst, so that the patient's own serum should be absorbed on the same principle as autogenous vaccines.

Dr. W. S. Casselberry of Chicago said that up to this time the results of tuberculin on laryngeal lesions had been uniformly bad. He had seen, however, good effects in the larynx follow tuberculin injections even weeks and months after. He had reported elsewhere 40 per cent. of arrested cases in laryngeal tuberculosis, some of them having taken small doses of tuberculin. Many of the men who treated large numbers of tuberculous patients failed to examine the larynx, whereas if they would so do we might better note the laryngeal effect of tuberculin.

Third Day—Thursday, May 5.

Esophageal Diverticula.—Dr. Emil Mayer, New York City, read this paper (see page 10). He presented the following conclusions: (1) Examinations should be conducted in a routine manner, the esophagoscope being used last, bearing in mind always the danger of a rupture of a possible aneurysm. (2) In making the examination with the *x*-ray, the introduction of a small tube filled with shot might take the place of bismuth. (3) Esophageal diverticula might be easily diagnosed. (4) Modern surgery offered much hope for these patients.

Dr. Chevalier Jackson of Pittsburg thought that the passing of a bougie was a more dangerous procedure than a skillful esophagoscopy.

Dr. J. Gordon Wilson of Chicago exhibited a specimen of a diverticulum in a young lion twenty months of age. It was one of the first instances of the kind known to occur in the lower animals. The lion had died in a choking spell. In addition there was a thickening of what Killian calls the sphincter muscle of the esophagus.

Dr. Mayer said, in closing, that it was all a matter of the experience a man had had with reference to the choice of instruments. Care should always be taken in the use of the bougie, and if one found an obstruction, he should desist from its further use. He would, however, lay stress on the necessity of a routine method of examination strictly adhered to, and one should first satisfy himself of the absence of any serious condition.

The Cutting in Two of a Large Steel Pin While Transfixed in the Left Bronchus and Its Removal by Lower Bronchoscopy.—Dr. W. E. Casselberry of Chicago reported this case and exhibited the instrument referred to. The pin was glass-headed and about one and a half inches long and had been in position in the bronchus of a fifteen-year-old girl for about ten weeks, having caused in the first fortnight only a few spells of coughing with blood streaked sputa. The *x*-ray, however, clearly demonstrated its presence although with some uncertainty, but the bronchoscope settled the matter. The pin was firmly fixed and all efforts at removal with ordinary instruments failed as it was impacted at both ends and it was necessary to cut it in two, but the question was, how to prevent a portion from falling further down the bronchial tree when the division was made. So he had devised a beak-shaped scissor-like instrument so arranged as to avoid losing the smaller fragment by electing it to be held in the grasp of the pin-cutter. After the cutting the larger piece settled somewhat but was easily withdrawn with a Jackson forceps.

Dr. Chevalier Jackson of Pittsburg referred to the reader's statements with reference to the unreliability of a negative skiagram. We might get the history of a metallic body when it was not metallic and not dense enough to show. We had frequently to make an examination in the face of a negative report. In a case of a pin similar to the one reported he (Dr. Jackson) had utterly failed to remove it and he congratulated Dr. Casselberry on his success and the ingenuity displayed in the making of his new device.

Dr. T. H. Halsted of Syracuse referred to a case of his own in which an attempt to remove a large brass-headed upholsterer's tack had resulted in the very accident referred to by Dr. Casselberry, namely, the loss of a fragment. The tack could be grasped with the forceps but the head was so imbedded that it came off and no amount of searching could discover the shank. It was thought it might have been lost in the subsequent vomitus. However, the child made an uninterrupted recovery.

Dr. Emil Mayer of New York City said that to see a foreign body in a bronchus and to remove it were two different things. In one case in which the *x*-ray showed a tack in position quite plainly he could not see or feel anything with the tube as the foreign body had been so long in position that it had become surrounded by granulations and was not protruding so he felt that in view of the limitations of the case as to sight and feel of the body it would be harmful to the child's best interests to remove it. The child was perfectly well except that it was known that it had a tack in its bronchus.

Dr. C. G. Coakley of New York City referred to a case in his own practice in which a pin had been in a bronchus for a month when he was called to the patient. In spite of a tracheotomy and the dissecting away of a large thyroid gland, which bent the trachea from its normal course, he had been unable to remove the pin although he could see it and grasp it with the forceps. Finally in a paroxysm of coughing it was dislodged and disappeared. It was located by the *x*-ray lower down. Dr. Jackson had seen this case and it was the one referred to by the latter. He (Dr. J.) was unable to see the pin but could feel it, yet not extract it. In six months the patient developed an abscess of the lung followed by pneumonia and then died. In this case such an instrument as Dr. Casselberry's might have succeeded.

Dr. R. C. Myles of New York City referred to the intense anxiety and pain these cases had given before the

days of direct examination and referred to the extraction of a large needle from the larynx of a woman in whom the foreign body lay across the larynx and had finally torn itself loose under traction with a heavy forceps.

Dr. Casselberry said, in closing, that it required a skillfully planned campaign to remove these impacted foreign bodies. It had taken him some two weeks to weigh and balance all the factors in his own case, but after these had been considered, his treatment devised, and removal attempted, the latter required but four minutes and a half. A motive running through his paper sought not alone to describe the mechanism but to convey in logical sequence the train of thought and intelligent management to overcome successive adversities ere the culminating technical moment had arrived.

Epithelioma of the Left Vocal Cord.—Dr. Charles W. Richardson of Washington reported this case. The patient was a young man of forty years who developed a cold in October, 1908. Had hoarseness and a cough. Examination of the left cord showed it congested with some proliferation near the anterior commissure. Process looked more like a tuberculous than a malignant one. Four weeks of treatment relieved the symptoms though not the local appearance which slightly increased so far as proliferation was concerned. A small fragment revealed the epitheliomatous nature of the growth. A thyrotomy without the usual tracheotomy was done. The method employed for the removal of the growth was the usual subperichondrial one. Healing by primary union occurred and was completed in about two weeks. When last seen thirteen months later there was no recurrence of the growth.

Dr. J. Solis-Cohen of Philadelphia said that as far as he knew the superichondrial method was original with himself and he had first performed it several years ago, the patient being still alive. He had at first applied tincture of benzoin to the denuded cartilage. Later he had used acid nitrate of mercury thinking that there might be lingering deposits of malignancy.

Dr. W. L. Ballenger of Chicago had performed the same operation a year ago and his patient was still well two months ago with no recurrence.

Dr. T. P. Berens of New York City had reported to another society a description of a recent case of a man with epithelioma and a hoarseness of some five years' standing, in whom he had removed intralaryngeally the whole anterior two-thirds of the cord and found that his suspicions were confirmed. Finally he slit the larynx, having in mind to do the Cohen operation. He found that the periosteum was more adherent over the center of the false cord and removed the wing of the cartilage on that side. By applying adrenalin to the wound surface of the mucous membrane he had a dry wound when cut through. In three days he was able to remove the tracheotomy tube and his patient made an uneventful recovery from the operation. He now spoke in a very useful voice and could use the telephone without difficulty.

Dr. C. G. Coakley of New York City said that he wished he could report as good results as he had heard in this discussion. In a case of his own hemilaryngectomy was done, and later there ensued a contraction requiring the insertion of a tracheotomy tube. He did not believe that a total laryngectomy would prolong the patient's life, but a year ago the man was in very good condition.

Dr. H. L. Swain of New Haven referred to a case of his own operated on now some three years ago without recurrence. Now the patient has a perfectly loud and clear voice. There has been added a cicatricial band filling the area formerly occupied by the true cord, which had been removed, and it had a free, clear edge, with some range of motion so that the man had now a pretty fair pair of vocal cords. He would like to know if such a result had been a common one with the men who had done the operation.

Dr. Emil Mayer of New York had had two years ago a young man with every appearance of cancer, but who cleared up under the iodide. This was an experience which might happen to any of us.

Dr. D. Bryson Delavan of New York City referred to the varying microscopical findings in superficial and deep portions of these laryngeal growths, saying that they often differed, citing an illustrative case. The special rather than the general surgeon should operate on such cases as were under discussion. He himself did not believe in the preliminary removal of a fragment for microscopical examination. The present discussion had completely proved the correctness of Dr. J. N. Mackenzie's position in this matter; every one knew that the irritation of these growths was bad, but when it was admitted that the patient should be told to prepare himself for a completer operation very shortly after the removal of a piece of the growth for microscopical examination, the case was simply given away.

Dr. Richardson in closing said that his patient had developed rather a hoarse voice. The hand referred to by Dr. Swain was commencing to grow and at his last examination was distinctly in evidence and he supposed it would gradually develop more fully.

A Case of Laryngeal Syphilis.—Dr. Harmon Smith of New York City dwelt on the difficulties of differential diagnosis. His patient was a male of 25 years who five years after the initial lesion had an attack of laryngitis and shortly after had on his right vocal cord a soft polypoid mass about the center which seemed to project from the ventricle. There was slightly retarded movement while the voice was strong though husky. The case was regarded as specific in origin but later developments and local changes led to a suspicion of either tuberculosis or malignancy. The points of differential diagnosis were passed in review. At no time during the observation had there been the appearance of any projection that would justify an attempt at obtaining a specimen for examination under the microscope. The patient's subsequent history had seemed to confirm the truth of the original diagnosis although there had been no evidence of an external destructive process which we regularly expected to find when a specific process had existed for a long period. Although all the true cord could be seen in the mirror it would undergo queer physical changes while being examined. It would seem to change from a normal condition to a puffy, redder and mucus-soaked look during phonation. This condition had been explained as a disturbance, probably vascular and lymphatic in nature.

Fatal Case of Asphyxia Due to Pressure on the Trachea and Bronchus by a Tuberculous Mediastinal Gland.—Dr. C. G. Coakley of New York City reported this case. His patient was a girl of three years whose lungs revealed no lesion but she suffered from dyspnea, mainly exposure, suggesting some growth in the subglottic region. Attempts at examination with the bronchoscope under chloroform anesthesia led to cessation of respiration and the attempt was given up. A short time after an emergency tracheotomy was done under great difficulty as the child was struggling. Cocaine anesthesia was employed. Death occurred somewhat over an hour later. Autopsy revealed beneath the left tracheal mucosa an ovoid mass 2½ cm. in length which encroached on the tracheal lumen to such an extent as to almost entirely occlude it. A nodule was found at the apex of the left lung. Microscopical examination of a portion of the lung nodule revealed the presence of lymphoid tissue in which there were numerous epithelioid tubercles. The peritoneal glands were markedly enlarged and showed remnants of lymph gland tissue with closely massed epithelioid tubercles containing giant cells but with no caseation. The center of one nodule was caseous and infiltrated with leucocytes.

Dr. D. Bryson Delavan of New York City had had a very similar case, the autopsy revealing a tuberculous lymph node pressing on the trachea as well as general tuberculosis.

Dr. Chevalier Jackson of Pittsburg said that the case showed that we were gradually eliminating the things which used to be classed as status lymphaticus. In cases such as the one under discussion the alternating periods of free and obstructed breathing were very deceptive, and a tracheotomy ought to be done immediately. In one instance in which he had been called to see a child with dyspnea he had passed a bronchoscope and found the bronchi obstructed with cheesy material. Tracheotomy was done but the child lived only a few hours. Both lungs were found solidly tuberculous while lymph glands had broken down and filled the trabronchi with the material found.

Dr. E. Fletcher Ingals of Chicago reported the case of a child sent to him for removal of a foreign body from the bronchi, the symptoms being typical of this condition. The child was anesthetized with a view to bronchoscopy but died on the table. Post-mortem revealed a very large thymus.

Dr. J. Solis-Cohen of Philadelphia asked Dr. Coakley to mention the character of the dyspnea in his case. Was it suprasternal or infrasternal; with regard to thymus gland pressure cases he (Dr. Cohen) had seen instances in which the dyspnea was immediately relieved as soon as incision was made through the thymus?

Dr. B. R. Shurly of Detroit referred to those cases of apparently laryngeal dyspnea seen before the days of bronchoscopy in which the passage of an intubation tube gave no relief; an explanation of such cases was found in the one under discussion. The possibility of mediastinal disease in children was not appreciated by most of us. There was as yet no classified definite symptomatology of these cases but we might be helped in our diagnosis by the *x*-ray.

Dr. J. Price-Brown of Toronto asked if such a series of causes and post-mortem findings might occur in adults?

Dr. Coakley said in reply to Dr. Cohen's inquiry that dyspnea in his own case had been both inspiratory and expiratory, more expiratory. There was absolutely no cough although the history of the case in the beginning suggested pertussis.

Recurrent Papilloma of the Larynx Extending Over Thirty Years, During Which Time Two Thyrotomies Were Performed.—Dr. Francis R. Packard of Philadelphia reported a case of this nature. The interesting points in the case were (1) The long time during which the patient had been under observation and throughout which intelligent treatment had been directed toward the relief of his condition. (2) The fact that throughout that period, practically as far as could be learned, there had been no change in the nature of the neoplasm. (3) The fact that this growth was so typical as to etiology (followed a severe cold from getting wet), occurring in an auctioneer, as to progress and recurrence in spite of repeated removals, as to growth and microscopic appearance and (4) as showing no tendency in spite of repeated operations and traumatism to undergo any malignant degeneration.

Dr. Samuel Johnston of Baltimore referred to a case of a child in his own practice in whom cure had been effected by applications of chloride of zinc.

Dr. D. Bryson Delavan of New York City said that the types of papilloma mentioned by Dr. Packard and Dr. Johnston were altogether different things. In one of these recurring cases under his care the larynx had been split and kept open while radium was used. During the last three months there had been no recurrence. It was too early yet to predict the ultimate outcome.

Dr. C. W. Richardson of Washington said that these recurring growths apparently reached a certain stage or limit of reproduction and that if we kept at them until that time they would cease.

Dr. J. P. Clark stated that in his experience with papilloma he had never known a case in which the growth had begun in early life. It was a matter worthy of notice that in the reader's case the growth had not begun until he was forty. In the case of treatment of the lesion in the larynx of the child it was hard to say just how much good treatment did, for papilloma would come and go as did the ordinary wart. When it got ready to go it went.

Dr. W. E. Casselberry of Chicago had seen a number of cases of papilloma originating in adult life. We could not divide these cases into merely two categories, he would rather say ten or more. They ranged all the way from the narrow circumscribed, base-pedunculated growth to the persistingly recurring growth filling the larynx. He advocated the use of the galvano-cautery for the destruction of the base. Much surface could be destroyed without any impairment of the cords.

Dr. W. K. Simpson of New York City had used lactic acid; in one case the recurrence had ceased with perfect restoration of the vocal cords and voice. He had come to the conclusion that lactic acid was one of the best escharotics we had.

Dr. H. L. Swain of New Haven mentioned one case of recurrence in which he had been compelled to do a thyrotomy and burn out the base with the Paquelin cautery. Even after that the patient had had one or two small recurrences. He thought it better to avoid instrumentation if it was possible.

Dr. B. R. Shurly of Detroit had treated several such cases with tracheotomy and removal of all the growth possible. Ordinarily the putting of the larynx at rest was sufficient for recovery.

Dr. R. C. Myles of New York City was an advocate of tracheotomy and putting the larynx at rest. There was danger of pneumonia after the more serious operations. Care should be taken not to remove the growths from opposite sites on both cords at the same time.

Dr. Packard said in closing that his patient who was an unusually intelligent man had urged him not to do any intralaryngeal work if it could be avoided as the growth recurred after every such procedure. The speaker thought it better to have a piece removed and to get out as much of the mass as possible if it showed malignancy.

Black Tongue, Lingua Nigra Villosa.—Dr. Charles H. Knight of New York City reported a case of this disease. He said that Blegvad had been able to collect 183 cases including ten of his own in 1907. He passed in review the various theories as to the cause of the condition, quoting various authors, the persistence of the lesion, the variability of the symptoms and the doubtful efficacy of treatment. He believed the malady to be innocuous and that no apprehension of malignancy ought to be entertained. At present there was no evidence pointing to the existence of a causative organism. Blegvad had decided that the parasitic theory was not tenable. He thought that the reported cases called attention anew to the etiological importance of the vasomotor system. In our study of germs and of the rôle played by the internal secretions the rôle assumed by the nerves in the causation of certain elusive and obscure affections might have been neglected. There seemed to be no necessity of entering upon an energetic therapy of the malady although something might be done to relieve the mind of the patient. He closed by giving a selected bibliography of the literature of the subject.

Ozena and Respiratory Gymnastics.—Dr. Marcel Natier of Paris sent this paper. The author related a case of ozena occurring in a young boy who at an early age developed an acute attack of dysentery but who as he

grew up developed an ozena also. Regulation of the diet and general sanitation were followed by regulated respiratory gymnastics which led to a cure of the nasal malady. The author made a plea for a more careful investigation into the personal antecedents of this class of patients saying that the ozenatous condition often followed and was directly referable to some disease of childhood and said that there could be no plan of treatment applicable to all cases but that each one ought to be considered by itself and treated accordingly. In this way the ozenatous condition would frequently disappear as the child grew up. To focus the therapeutic efforts on the nose alone was to commit a grievous error.

Supplemental Report on Operations on Malignant Growths of the Upper Air Tract.—Dr. J. PRICE-BROWN of Toronto reported on three cases of nasal sarcoma the histories of which were presented to the Association one year ago. In two of the cases there had been a return of the growth in the middle turbinate and upper part of the posterior naris. He followed again his electro-cautery method, under twenty per cent. cocaine anesthesia and in one case forty per cent. when in the region of the sphenopalatine ganglion. The cases were still under treatment The patients were regularly at work and there had been no hemorrhage after treatment. He never packed the nostril after operation. He thinks it would be pernicious to take fresh sections for examination.

Election of Officers for the coming year resulted as follows: *President,* Dr. D. Braden Kyle of Philadelphia; *First Vice-President,* Dr. R. C. Myles of New York City; *Second Vice-President,* Dr. J. M. Ingersoll of Cleveland; *Secretary and Treasurer,* Dr. J. E. Newcomb, 118 West 69 St., New York City; *Librarian,* Dr. J. H. Bryan of Washington; *Member of Council* to serve for four years, Dr. J. E. Logan. Place and date of next meeting to be selected by the Council. Drs. O. Chiari of Vienna, E. J. Moure of Bordeaux and F. Massei of Naples were advanced from Corresponding, to the list of Honorary Fellows while Drs. E. von Navratil of Buda-Pesth and L. Réthi of Vienna were elected Corresponding Fellows.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held on April 18, 1910.

THE PRESIDENT, DR. REYNOLD WEBB WILCOX, IN THE CHAIR.

The Use of Radium Emanations in Internal Medicine.—By Dr. S. WACHSANN.

Alcoholism in Women, Including Its Treatment; Medicolegal Aspects.—Dr. G. ALFRED LAWRENCE read this paper. He stated that the subject of alcoholism in women was one that merited the most serious consideration of not only the medical profession but of civic, social, and legislative bodies as well. The greater susceptibility of women to the baneful effects of excessive alcoholic stimulation was a well recognized fact. Women were the mothers of our children, and alcohol, as we know, was one of the most pernicious hereditary factors in the production of defective offspring, and how could it be otherwise? The ovum containing the toxic alcoholic poison, perhaps impregnated by the spermatozoa of an alcoholic father, or the blood of the pregnant mother laden with greater or less amounts of the same toxic alcoholic beverage, continually flowing among the developing tissues of the growing fœtus, or the nourishment derived by the suckling infant from the breast of the alcoholic mother, could not help but have a marked pernicious inhibitory action upon the normal and active development of the offspring, resulting in a stunted, atrophic, unstable organism, defective both anatomically and physiologically.

Dr. Lawrence said that the medicolegal responsibility of the female alcoholic was a subject of the greatest importance, and the present laws appertaining to the same were far from satisfactory in many ways, and should be revised to conform with the medical advance in the knowledge of the various diseased states presented by the alcoholic. At present, legal recognition of inebriety was largely taken up with the disposal of the woman only after she had lapsed into a criminal offender against the law, and was punitive in character. So long as she merely ruined her own health and destroyed the happiness of herself and family, and dissipated her fortune, without committing some overt act against the public by a disturbance of the peace, and thus being placed under arrest as a disorderly or drunken person, or committing some crime of a given nature, the law, as it existed to-day, practically permitted her to pursue such a course without restraint. When, however, a crime was committed, in most cases she was held fully responsible, and not infrequently a more severe penalty was meted out than if the act were committed by a non-alcoholic, although, from a strictly medical standpoint, she might be entirely irresponsible. In New York State the means of properly caring for this large and ever increasing class of patients were crude and inadequate. The usual short sentence that was inflicted neither reformed the individual nor protected society, and when fined, if the same was paid, such was done usually by a relative who could ill afford to do so, but made the sacrifice in order to save the inebriate and her relations from further disgrace. Such a public exposure tended to lower the selfrespect of the individual, and frequently caused loss of employment or entirely demoralized the household, with the accompanying neglect of the husband and children when the woman was a wife and mother. No discrimination was made in the treatment of the occasional and the habitual inebriate, and the institutions to which such were now committed were not adapted to the properly classified treatment of the various cases coming to them, and there were no suitable provisions for their commitment at present. Such short term commitments and petty fines resulted in the "rounder" returning frequently to the hospitals, police stations, courts, prisons, and workhouses. Remedial measures were practically a negative quantity under such a procedure, whereas punitive measures were emphasized, and the courts were thus overcrowded with many cases that never should appear before them. Many patients who should receive careful medical attention were thus hastily disposed of in an improper manner. Many of these cases could be properly and successfully treated at their homes, or in a hotel, private hospital, or sanatorium, under the directions of a medical expert. In large centers like New York a vast majority of these inebriates required custodial care under proper legal commitment and for a proper length of time. During the past three years efforts had been made in this direction, and bills had been presented in the State Legislature for appropriations for the establishment of a suitable board which should have general control of the problem of dealing with public intoxication, and to establish a suitable hospital and colony for the care of such cases under proper commitment, but nothing had been done up to the present time. In concluding his paper, Dr. Lawrence said that surely our alcoholic women as well as men should have the most scientific medical-legal care and treatment under proper control in a suitable environment for the eradication of this entirely preventable habit, which all too soon might become an enslaving disease, with far-reaching pernicious results.

Effects Upon the Mind and Nervous System.—Dr. GRAEME M. HAMMOND said that in the majority of instances, alcoholic psychoses in women differed but little from the alcoholic psychoses in men, but in their forms they did differ to a certain extent. Women were particu-

larly sensitive to the effects of alcohol, and although he could not agree with the statement made by Dr. Lawrence that it was a habit which could be readily cured—because he believed that in many instances women were born inebriates—still, in a considerable number of cases it was a habit which treatment could affect. Speaking of the alcoholic psychoses in women, Dr. Hammond first took up pathological drunkenness, which was characterized by manifestations of blind motor explosions, attacks of melancholia or of mania. The duration was short; it was followed by stuporous sleep and generally by complete forgetfulness of what had taken place. This form of drunkenness was generally observed in those who showed a congenital intolerance for alcohol, in hysterical and neurasthenic subjects, and in mental defectives. Women, who as a class were generally more intolerant to alcohol than men, rarely in this form of drunkenness exhibited the tendency to violent actions. This was probably because the instincts of the man differed from those of the woman. Delirium tremens was an acute psychosis in chronic alcoholism, and, in the speaker's experience, it was decidedly less common in women than in men. This was probably due to the fact that, generally speaking, it took less alcohol to intoxicate a woman than a man, and, again, women seldom indulged in prolonged sprees to the same extent that men did. Even in dipsomaniac women delirium tremens was not very common. When it did occur, it differed in no essential details from the same psychosis in men. It was seen, probably, more often in women of the lower classes of society than in those of greater wealth more on account of the difference in the quality of the intoxicant than in the quantity consumed. Acute alcoholic hallucinosis was a psychosis lasting but a short time, and characterized by voluminous hallucinations of hearing, and often by paramount delusions of persecution, jealousy, and sexuality, but without disorientation. It was of far more common occurrence, in the speaker's experience, in women who drank to excess, than was delirium tremens, and was certainly more frequently seen in women than in men, bearing in mind the proportion of women drinkers to men drinkers. Probably the greater emotional nature of women was responsible for their so readily acquiring this hallucinatory psychosis. Korsakoff's psychosis, in which, from alcoholic toxemia, a multiple neuritis developed, with confabulation, loss of recent memories, and defective memory retention was again more often seen among women of the poorer class than among the well-to-do. While in connection with this disorder he used the term "alcoholic toxemia," he believed, in many instances, at least, that it was more likely to be caused by other deleterious substances contained in the liquor than by the alcohol. Were this not so, Korsakoff's syndrome, in view of the enormous quantity of alcohol consumed by the public at large, would be of much more frequent occurrence. The disease presented the same clinical picture in both sexes, but the prognosis for complete recovery, never excellent, was better for men than for women, because men had greater physical vigor and stronger vitality. Dr. Hammond said he had never seen a case of true paresis result from alcoholism. He had seen pseudoparesis result from alcoholism, but those patients might recover, while he had never seen a case of true paresis recover. In dipsomania, a hereditary psycosis, in which the tendency was to drink to excess, there was no difference in the symptoms between the two sexes, and it was pretty nearly as frequent in one as in the other; in fact, it was probably more frequent in women than in men, on account of the more delicate organism of the former. To-day, women were drinking more than ever before. This was probably due, to a large extent, to the fact that in recent years women had more absolute control of their own property and fortune, they had become more aggressive, and were no longer kept in the background. Years ago, women of the better class seldom drank in public; now, it was the exception not to see them do so. The cocktail and the highball were familiar to many women whose mothers knew nothing about alcoholic drinks whatever. It was the fault of the men who encouraged women to drink; it was the fault of the great wealth of the country; it was the fault of the great hostelries in our cities, where women could be seen drinking at all hours of the day; it was a condition of recent years. This free use of alcoholic beverages was producing a state of health among women which was somewhat new. In symptomatology it was like neurasthenia, with one or two important differences; there was the same nervous irritability, and inability to concentrate one's self upon any fixed occupation, but it entailed more moral degeneration than did neurasthenia. The mental deterioration was greater than occurred in simple neurasthenia. It was as though these patients had lost the finer tone of their ethical sense. There was no such moral degeneration as was seen in chronic alcoholic dementia, but the patients became less truthful and less careful in attending to the needs of their children and household. Dr. Hammond said we knew that the alcoholic male was capable of producing defective children, but we had not yet proved conclusively that this was so on the opposite side. In regard to the cure of women inebriates, the speaker said he had his doubts. Many would improve under seclusion, but he did not feel hopeful in regard to the ultimate outlook. Very few cases of pronounced alcoholic psychosis in women were susceptible to an absolute, permanent cure.

Effects Upon the Circulatory System.—Dr. Louis Faugères Bishop discussed this phase of the subject. He said that the effect of alcoholism on the circulatory organs was primarily functional; that it interfered with the vasomotor system, and resulted in a disturbance of tone of the heart and blood-vessels. The result was that the tonicity of the heart and blood-vessels was reduced, and that the blood pressure was lowered. In acute alcoholism this loss of tone often resulted in death when a strain was put upon the circulation by acute dilirium. In chronic alcoholism there was overloading of the heart with fat, and a fatty degeneration of its fibres. The same effect also occurred in the blood-vessels, and there was a loss of tone in both organs. However, in the course of time, if the kidneys became damaged, the heart and blood-vessels became hypertrophied to produce the high pressure required for the proper action of the damaged kidneys, and there developed the clinical picture of chronic Bright's disease. The effect upon the kidneys was the production of chronic interstitial nephritis of a more or less pronounced degree, but in people using good wines and not subject to other poisons than alcohol this might not be such as to lead to high arterial tension. Thus we saw heavy drinkers who escaped accidents and reached a great age. The effect on the liver was in the production of cirrhosis. The question of the relation between alcoholism and the circulatory organs was a complicated one. Probably a more frequent cause of disease of these organs was found in the absorption from the gastrointestinal canal of the products of bad food chemistry, and was closely connected with the appearance of indican in the urine. This happened very often in those whose digestive organs were disturbed by alcoholic indulgence, and the over-ingestion of food that we found in such subjects. The whole question of alcoholism, Dr. Bishop said, was so complicated that it was hard to isolate one topic from another, and if, in his attempt to do so, he had appeared to minimize the evils of alcoholism, such was not his intention.

Dr. Charles E. Atwood said that what to do with

cases of alcoholism in practice was one of the most serious problems of the physician. In a word, very little could be accomplished without the co-operation of the patient and her family and household. With such co-operation, a cure could be effected, but relapses were frequent. A very thorough and careful examination of the physical condition of the patient was absolutely essential. The chief physical disorders met with in these cases were affections of the digestive system, the kidneys, and the heart. More or less neurasthenia was also present. It was usually desirable to withdraw all alcohol quickly, but sometimes such a procedure was undesirable or even dangerous, and in nearly all cases, when it was withdrawn, some substitute stimulant, such as strychnine, was required to sustain the patient. Cases of inebriety induced by physicians' prescriptions for milk punches or malt liquors, or the daily use of wine, long continued, were difficult to treat, as patients claimed a physician's original sanction for their indulgence. Other cases, such as those resulting from social drinking, required some change of environment as a first essential of treatment. A measure of success had been attained at the Vanderbilt Clinic by combining several elements of therapeusis. A number of patients had been brought there, at the speaker's suggestion, by social workers, and their treatment at the clinic had been medical, hydrotherapeutic, and suggestive. Hypnotism was employed, when possible, and the improvement of the patient was tested for, at each visit, in the psychological department. Cases of inebriety which presented a true psychosis might be treated, as a last resort, in hospitals or sanatoria licensed to receive the insane. Alcoholic psychoses were developed on a basis of chronic alcoholism; they usually occurred where there was a neuropathic condition, often associated with a faulty heredity, which weakened the will power and diminished physical resistance to all toxic agencies. The most common forms of alcoholic psychoses in women were alcoholic deterioration, alcoholic delusional insanity, acute alcoholic hallucinosis, pseudoparesis, and Korsakow's psychosis, which was a form of mental disorder accompanying alcoholic neuritis. Delirium tremens was much less common in women than in men. Nearly all of the alcoholic psychoses were curable. As to the frequency of inebriety in women, outside of the large cities and the wealthy classes, the speaker thought that it was not on the increase. In his experience among the poor at the Vanderbilt Clinic, during eighteen years, there had been really a decrease in the number of women alcoholics treated, and the number had never been great. During his term of service at Bloomingdale, the psychopathic branch of the New York Hospital, which drew patients mostly from well-to-do classes of New York City, the number of women with alcoholic psychoses had been larger in proportion than the number treated by him at the Utica State Hospital, which received patients mostly from the poor and middle classes from small communities and from the rural districts. At Bloomingdale, 40 women out of 755 admissions had alcoholic psychoses, and 56 others were moderate or excessive drinkers, but developed other forms of insanity. At Utica, of 792 women admitted, alcohol was given as a sole cause of psychosis in only 15 cases, and as an associated factor in 18 cases. At the New York Hospital for Nervous Diseases on Blackwell's Island, there were comparatively few cases of nervous disease among the women, due to alcohol. On Randall's Island many of the idiots had an alcoholic neuropathic heredity. Alcohol was known to be a protoplasmic poison. It was estimated that only about ten per cent. of the children of hard drinkers were normal mentally and physically, and the character and physique of the child was greatly affected by the condition of the mother while carrying it. If the pregnant women drank considerable alcohol, some of it passed as such into the fetus *in utero*. Of children thus born of drunken mothers, more than half died in infancy or were still born, while a number of survivors were mentally defective or epileptic, or exhibited mental degeneracy later in life.

Dr. Arthur C. Brush of Brooklyn said the greater susceptibility of women to the effects of alcohol was well known, and was doubtless largely attributed to the education of women. Boys, from the earliest childhood, were taught to control themselves; it was far different with the girl, who was allowed to give way to her emotions at any time. Women yielded more easily to the alcoholic habit than men, and in some cases it undoubtedly formed a distinct disease. Some of these defectives never felt well unless they were whipped up by alcohol; this might form a continuous condition, or the paroxysmal one of dipsomania. The speaker said he had always looked upon dipsomania as almost an epileptic impulse to drink. Discussing Dr. Lawrence's idea to control the sale of intoxicants to those who were addicted to the habit, Dr. Brush said it would be very difficult to identify such persons, especially in the large cities. As to the question of the responsibility of the drinker, the law held that so long as the person knew the nature and consequences of his act he could be held responsible. The plan of having drinkers committed by special commission would work probably as did our insane law, where such persons always had the right to demand a trial by jury. At present there was no means in this State of controlling the drinker. Dr. Brush said he had been in charge of the alcoholic ward of the Kings County Hospital for twenty years. His experience there was confirmatory of that of the other speakers that delirium tremens was less common in women than in men. On the contrary, multiple neuritis was more frequent in women than in men, probably because she took her alcohol in more concentrated form and frequently in the form of patent medicines that contained a poor quality of alcohol. He had never seen a case of true paresis resulting from alcoholism. That drink was on the increase among the better classes, was well known, but he did not think this was the cause among the lower classes. At any rate, the male wards in the hospital with which he was connected was not quite as full of alcoholics now as it was ten years ago, and that institution drew its patients from among the lower classes. The number of alcoholic women seen there were few. Among the causes for the increase of the use of alcohol by women was our modern mode of living. Women now generally preferred to live in flats, they neglected their household duties, and had an insane desire for pleasure.

Dr. John Herman Branth said the defects in children of alcoholic parents were not only mental, but also physical. In 1901, at a meeting of the New York County Medical Society, he had read a paper on cleft palate and harelip, and mentioned that Lawson Tait and others had searched in vain for causes for such deformities. Dr. Branth, upon close questioning of the parents of such children, learned that in the majority of cases the parents, one or both, confessed to an intoxicated condition at the time of the sexual act to which conception followed. Again, alcoholism not only attacked the nervous system, but the entire metabolism of every part of the body was, of course, influenced. If we examined the cadaver of a chronic alcoholic, we would find the fat and muscle soft and oily, the tissues were so friable that one could crush them between thumb and finger. When on the dissecting table, the oily liquid continually oozed out from the deeper tissues. Then, again, the recuperative powers of an alcoholic were far below normal. Let an alcoholic meet with an attack of pneumonia or a fracture of the thigh, and recovery was one of the rare results. That the ingestion of different kinds of substances affected the general metabolism in the individual could be seen macro-

scopically in hogs. Some of these animals were farm fed, others exclusively corn fed, and others were fed on distillery swill. The first made the best pork for human consumption, the second a lower grade, and the third (the swill fed) the poorest and cheapest pork, the latter looking bluish-white, and being soft and friable.

Dr. William M. Leszynsky said he agreed with the previous speakers as to the greater difficulties in managing women addicted to the excessive use of alcohol. As an illustration of the influence of impressive suggestion, he narrated the history of a patient who had been under his care for several years. She had then drifted from one physician to another without improvement. After an operation for the removal of a large ovarian cyst, she was told by the surgeon that if she returned to the use of alcohol another dangerous operation would be necessary. This occurred over six years ago, and she had since refrained from the use of alcohol. Some time ago, the speaker said, he was asked to see a patient with pronounced signs of multiple neuritis. He was told that she was a total abstainer, but he soon discovered that although she never drank beer, wine, or whisky, she had for a long time been in the habit of taking a tablespoon of the "essence of peppermint" every two or three hours. Essence of Jamaica ginger was another alcoholic stimulant used by some women, and the same was true of a number of "tonics" sold in the drug stores.

Dr. Daniel H. Smith said he wished to take exception to the statement of one of the speakers regarding the quality of the liquor that was offered for sale in the average drug store. With the exception of those stores that sold the liquor in the original package, the stuff sold under the name of liquor in many of the drug stores was unfit to drink. Instead of whisky, they usually dispensed French spirits at the rate of about 75 cents for four ounces.

The President, Dr. Wilcox, said that under the Pure Food Law it was to be hoped that there would be some reform in the quality of the liquors sold in the drug stores. Under the present laws, the speaker said, it was practically impossible to control the female inebriate without the co-operation of her entire family. Women could purchase all the liquor they wanted at the grocery stores; this class of dealers were apparently not amenable to the laws that controlled saloon keepers, and practically defied any attempt to restrain them from sending liquor into the home. Apparently, the more pretentious alleged grocery stores were conducted with less sense of moral obligation than the lowest grogeries.

Dr. Lawrence, in closing, emphasized the importance of preventative measures, which he regarded of even more importance here than in connection with tuberculosis. The public should be educated in regard to the evils of alcoholism, and he saw no reason why we should not be able to control the alcoholic in this country just as well as they did in New South Wales. A commitment could be secured in many appropriate cases, even where the patients took advantage of their right of a trial by jury.

Dr. Hammond, replying to the question of whether there was any difference in the quality of the beer and liquors brewed and distilled to-day, as compared with those in olden times, especially in England, where a drunk was guaranteed for half a shilling, and yet we did not read of any of the alcoholic psychoses then which were so common to-day, said that these psychoses probably existed then as now, but there were no statistics kept of such cases and no public institutions to which they were sent. As to the proper care of the inebriate to-day, the law was undoubtedly inadequate. These patients did not want to go to an institution, and there was no law that compelled them to go. They could only be tried in open court as habitual drunkards.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of August 27, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	518	153
Diphtheria	225	23
Measles	75	6
Scarlet Fever	74	1
Smallpox	—	—
Varicella	13	—
Typhoid Fever	118	14
Whooping Cough	33	9
Cerebrospinal Meningitis	3	2
Malarial Fever	—	—
Totals	1,059	209

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, during the week ended August 26, 1910.

A BRIEF STUDY OF THE CONTRIBUTION OF IGNAZ PHILIP SEMMELWEIS TO MODERN MEDICINE.*

BY RICHARD COLE NEWTON, M.D.,

MONTCLAIR, N. J.,

CONSULTING PHYSICIAN TO THE MOUNTAINSIDE HOSPITAL.

IGNAZ PHILIP SEMMELWEIS was born in Budapest, Hungary, in July, 1818, and died in Vienna in August, 1865.

His father was a tradesman in a fair way of business, and his mother came of good, respectable stock. The particulars of his early life do not seem to be well known, nor are they of especial concern to us. He studied medicine at Vienna where he was known as a light-hearted and companionable young man, who, however, was an earnest student, capable of an extraordinary amount of painstaking and laborious effort. He had developed a strong taste for midwifery, and, in 1844, he took the degree of master of midwifery and applied for the position of assistant to the Clinic for Obstetrics attached to the Vienna General Hospital. This was an important position and its occupancy was esteemed a great advance for a young man, and an indication that he would achieve substantial honors in the obstetrical world.

Owing to the fact that his predecessor in this post had obtained a two years' extension of the regular tour of duty, Semmelweis was obliged to wait from 1844 to 1846 for his chance to fill the position. During these two years he made good use of his time by studying in the clinic—this he could do quite advantageously while not tied down by the routine duties of a regular assistant. Although he could not spare the time for regular attendance at the Gynecological Clinic he devoted himself with considerable assiduity to the pathological study of the bodies of the women who had died from gynecological diseases and operations. Owing to the friendship which Professor Rokitansky entertained for the young man, Semmelweis was afforded abundant opportunity for study upon the cadaver, of which he made good use.

In 1846, Semmelweis obtained the regular appointment as clinical assistant in the first obstetric clinic. There were two clinics; the first for the instruction of medical students, and the second for the instruction of midwives. The assistant in the first clinic had to visit and examine every patient in the early morning so that he might report on each case to the professor, upon the arrival of the latter in the wards, later in the day. The assistant on these rounds was accompanied by a crowd of students, each one of whom might examine any or all of the patients. As Sinclair sententiously remarks, "here we have a glimpse of practices which may well make the modern accoucheur shudder." In the afternoon it was the duty of the assistant to take the students through the wards again for the purpose of clinical instruction and to reexamine every patient who was in labor.

Not satisfied with the performance of his prescribed duties, as outlined above, Semmelweis continued his researches into pathological anatomy in the pathological institute during the early morning hours before visiting his patients. This he did chiefly to perfect his knowledge of the pathology of gynecology and obstetrics. He was a most assiduous worker in pathology and, as he afterwards stated, had by the practices just recounted unwittingly consigned many an unfortunate woman to an untimely grave.

During the year 1846 there were 460 deaths in the first clinic and 105 in the second from puerperal fever alone, in spite of all the then known treatment in midwifery practice.

Other young obstetricians, the predecessors and contemporaries of Semmelweis, were aware of these facts, yet seemed to regard them with indifference. In the spare time which they enjoyed between professional work and social engagements they discussed, like the surgeons of our own day, small variations in operations and modifications of instruments, more or less trifling, or the introduction of new therapeutic maneuvers, but Semmelweis took little interest in such discussions.

It was under such circumstances that his immediate successor, Carl Braun, invented his blunt decapitation hook and other clinical assistants made contributions to the technique of obstetric practice which have since been forgotten. Semmelweis had been cast in quite a different mold from his colleagues. He could not accept verbiage for reality, nor amuse himself with toys. His heart bled for the sufferers he saw sicken and die daily while under his care. The constantly recurring questions before his mind were: What is puerperal fever? How does it arise? What can be done to prevent it? What treatment can prevail against it? With the kindly sympathies of a strong man and the tender heart of a woman he "was to exhibit in due course the most cutting indignation and sarcastic contempt for those students and nurses who by their levity and carelessness endangered the lives of the poor women" who were consigned to their care.

In order to be able to appreciate, at least in part, the enormous progress which this man made in unraveling the mystery which had hitherto shrouded the etiology of puerperal fever, it is necessary to consider briefly the various theories which had been advanced in the long course of years to account for its prevalence and mortality.

*Read before the Orange Mountain Medical Society.

While it will be impracticable to even mention all of the almost innumerable theories which had been brought forward from time to time, a short reference to some of the more generally accepted will serve to show something of the attitude of the medical mind in the early part of the last century, and also can scarcely fail to be of some historical interest.

Furthermore, as intimated above, only by this means can the enormous debt which the world owes to Semmelweis be even partly appreciated. A case that occurred under the care of Dr. Johann Chiari while Semmelweis was studying for the degree of master of midwifery, and which he had the opportunity of observing, serves to illustrate the simple faith of that day in the supposed terrible power of epidemic puerperal fever. It also casts a strong side light upon the then prevalent methods of practicing gynecology.

A woman suffering from a fibroid polypus of the uterus was admitted to the clinic and the tumor was removed in the usual way. The patient soon showed the symptoms usually noted in puerperal fever and shortly afterwards died. Post-mortem examination revealed lesions identical with those commonly found in puerperal fever. Dr. Chiari explained this state of things by declaring that the patient had actually died from puerperal fever, although she had not been pregnant, nor passed through the puerperium, because, as he alleged, the epidemic influence of the fever had become so strong that it had even attacked and carried off non-puerperal women. This, he explained, might happen in cases where the epidemic influences were exceptionally virulent. A marked instance one might say of an explanation which does not explain. The sort of talk which the casuists in medicine have been wont to employ, and still do sometimes employ, as a cloak to their ignorance.

Sinclair, from whose "Life of Semmelweis" I have been freely quoting, tells us that two principal theories of the etiology of puerperal fever were strongly prevalent up to at least the end of the first third of the nineteenth century. According to one of them the disease was a "milk fever." Without having been able to lay my hand upon a succinct statement of exactly what was meant by the term "milk fever"—a term apparently almost as common amongst physicians seventy-five or eighty years ago as the term autointoxication is among us to-day—I think that I am justified in defining it as a fever which every lying-in woman suffered from when her milk "came." As in those filthy days probably every woman had some infection and showed some fibrile rise when lactation was established, no doubt the fever was looked upon as a necessary accompaniment of the process, and in cases where the fever, instead of subsiding in a few days, increased in virulence and intensity, along with the development of lymphangitis, adenitis, pleurisy, peritonitis, and so forth, accompanied by fibrinous exudates and mitastases, and finally leading to death; the fever which was known to have started when the process of lactation should have begun seemed to have been caused by some pathological change in the milk itself or some derangement of the process.

This assumption would naturally be strengthened by the disappearance of milk from the breasts and the suppression of lactation so generally noted in puerperal fever. The learned men of those days talked about milk pneumonia, milk peritonitis, and so on, evidently believing that the disease producing milk had found its way into the lungs or into the abdominal cavity. One French observer asserted that he had found milk in its natural form inside the peritoneum.

This theory had many supporters in England, and that is probably why it was adopted by Böer, afterwards the professor of obstetrics in the Vienna School of Medicine, and the predecessor of Kline, under whom Semmelweis served in the obstetric clinic. Böer, it should be stated, had studied in England where obstetrics were somewhat better taught, it seems, than in Continental Europe, and had carried the English ideas to Vienna and taught them there. At all events Semmelweis, when he became assistant to the First Obstetric Clinic in Vienna, was what was called a "milk fever epidemicist," which seems to me to mean that he believed that some epidemic influence interfered with, prevented, or altered the secretion of the milk in parturient women, and changed this innocuous fluid into a most deadly systemic poison.

The other common theory of the cause of child-bed fever was that it came from the suppression of the lochia. Smellie, the well-known English obstetrician, was an advocate of this theory, and had probably brought his opinions from France, where they were taught in the School of Mauriceau, whose influence as a teacher spread this doctrine over Western Europe.

The so-called physiological school, as Sinclair tersely remarks, *a lucus a non lucendo*, held to a mixture of these two luminous theories, which were really, it seems, much alike in so far as they explained the fever by attributing it to the alteration or suppression of a natural bodily function.

The so-called gastric bilious fever theory had a considerable vogue in England at one time. The severe cases of puerperal fever were also called putrid fever. Arising apparently at about the same time and holding its ground for about a century was the assumption that inflammation was the central fact in child-bed fever. The advocates of this doctrine naturally divided themselves into cliques accordingly as they followed the teachings of different individuals who claimed that the trouble might start in one or another of the organs of the body, which might be the peritoneum, or the womb, or the intestines, or even the omentum. William Hunter and, later, Baudelocque, were perhaps the most prominent and influential advocates of the theory of a primary peritonitis as the cause of puerperal fever.

About the middle of the eighteenth century we find the first reference to erysipelas as closely associated with child-bed fever. Gordon of Aberdeen (1795) alleged that puerperal fever was an erysipelas of the bowels and peritoneum. By the middle of the nineteenth century the almost universal belief in England and America was that erysipelas and puerperal fever were identical maladies.

Another doctrine was maintaned more or less strenuously during this time, which was apparently at variance with the theory of the intimate relationship between erysipelas and child-bed fever. This maintained that the latter was really a disease *sui generis*, independent as an entity, but most variable in its phenomena, owing to fortuitous influences. This belief still prevailed in England, even when it was assumed that any zymotic disease was capable of taking on the form of puerperal fever while con-

cealing its own most characteristic features. As for example, scarlet fever, without its rash and without its angina, was supposed to seize the lying-in woman in the form of child-bed fever. "Nulla febris est quæ non alquando cadat in puerperam." (There is no kind of fever which does not sometimes attack the lying-in woman.)

This pathological hodge-podge was called the "variable" theory of puerperal fever as enunciated by Eisemann in 1837. No doubt my esteemed colleague on this historical committee, my old friend Dr. Harvey, recollects as I do similar theories of the etiology of puerperal fever which were still taught and believed when we were students.

Ultimately came the dawn of the wound-fever theory as the internal factor in the causation of this disease. Yet even in England, where the most rational pioneer opinions had developed, there were for years and very likely still are vestiges of a general belief in a *contagium*, and the pioneers of our modern pathology harked back to a "specific something" an "unknown something," the *divinum aliquid*, perhaps a specific primary change in the blood, which was alleged to produce the local lesions.

During those long years when these chaotic ideas prevailed regarding the internal factors in the etiology of puerperal fever, the explanation of the external factors was still more vague and incomprehensible. Certain more or less clearly defined influences of an atmospheric, telluric, or cosmic nature were alleged as causes of the disease. To them the term *genius epidemicus* was applied, and so evanescent were they alleged to be that mere changes in the weather were constantly referred to by some writers, especially German, French, and even Scotch authors, as sufficient to account for the greater or less prevalence of child-bed sickness. A specially injurious entity, more fearsome by reason of its mysterious origin, was alleged to be developed and spread abroad in some unknown way. It was called a miasma. This miasma, or *genius epidemicus*, might extend over a vast area, or it might be restricted to a single town, or even a single building, such as a hospital, where it was especially prone to develop if there was overcrowding of pregnant or puerperal women—the so-called "crowd poisoning" of our ancestors. This was the theory to which Cruveilhier lent the weight of his powerful authority.

It was believed by many that with a certain intensity and extension of the malady a contagion was brought into existence. According to this belief a contagion represented a specific virus which originated only in the diseased organism and that from that point of origin could produce in another individual the same disease. In some minds the contagion assumed the form of a mysterious halo, or areola, which clung to the unfortunate practitioner who had come under its malign influence and rendered him a source of danger wherever he went. Coming near to the time when the doctrine of Semmelweis was announced we find an almost general prevalence of the belief that the pregnant and puerperal woman was a thing unique in nature. This theory of loaded blood and tissues generally, this state of unstable equilibrium when the system was hanging on the verge of fever and was especially vulnerable to the influence of any adverse factor, held the field for years, especially among the "older, unteachable, obstetric mandarins of England." Yet it had to give way finally before the advance of modern thought and was the last barrier to the spread of the present doctrine of the pathology of child-bed fever.

It will take us too far afield to describe the doctrines of blood crasis and hyperinosis, which seem to have been lugged into this hypothetical pathology to explain why the pregnant and parturient female was assumed to be a being governed by suppositious laws which had no application to any other living creature. We still find Virchow in 1801 and Barnes in 1875 teaching the spontaneous origin of child-bed fever. My venerable colleague and I can still remember the talk about the *locus minoris resistentiæ* and the malign effects of sudden emotions, indiscretions in diet, and changes in the weather upon lying-in women. Is it to be wondered at, then, that when Semmelweis made his great discovery he found, like Copernicus and Galileo, a wall of prejudice and human vanity directly in his path, which made his progress exceedingly difficult?

To return to the personal history of the subject of this paper we find Semmelweis, in 1846, duly installed as assistant to the Chair of Obstetrics and in charge of the First Obstetric Clinic in the Vienna General Hospital. He had observed that there were between three and four times as many deaths in child-bed in the first clinic as in the second, and he also reflected that students fresh from the operating room and the dead house freely examined the patients in the first clinic, while the midwives, who had no such free access to cadaveric material, handled and delivered the patients in the second clinic. He also observed that it was especially the young and vigorous primiparæ, often powerfully built and strong young women, whose first labors were naturally tedious, who were most apt to suffer from the dreaded child-bed fever.

So marked had the difference in the mortality records of the two clinics become, that the patients themselves were aware of the dangers of being delivered in the first clinic, and begged and prayed with tears and lamentations not to be sent into its wards. Still the rule of sending every other patient into the first clinic and the alternates into the second was maintained. Except in the medical attendance there seemed to be no difference whatever in the surroundings, appointments, and management of the two clinics.

Semmelweis had noted all these things, but their true significance had not yet dawned upon him. In 1847 (March 20) Professor Kolletschka, whom Semmelweis especially honored and esteemed, received a prick of the finger in making an autopsy. He thereupon became afflicted with lymphangitis of the arm, followed by pleurisy, pericarditis, peritonitis, and meningitis, from which he died in a few days after the initial infection. Shortly before his death a metastasis occurred in one of his eyes. The autopsy revealed a series of lesions identical with those found after death from child-bed fever. As Semmelweis says, "Excited as I then was, it entered into my mind with irresistible clearness that the disease from which Kolletschka had died was identical with that from which I had seen so many lying-in women die." This instance, with its powerful shock to his feelings, broke upon Semmelweis like a revelation and led him to his great and immortal discovery. The difference in the mortality rates of the first and second obstetric clinics was explained. It was because the students without sufficiently cleansing their hands after handling cadaveric material examined the lying-in women in

the first clinic, while those in the second were not exposed to this source of infection. It also explained why the young and strong primiparæ were more prone to child-bed fevers in the first clinic than the multiparæ, simply because being in labor longer they were examined more times and by more students than those whose labors were shorter and less interesting. Semmelweis immediately ordered that every student before examining a woman in the lying-in wards should wash his hands thoroughly in chlorine water. As a result the mortality of parturient women in the first clinic fell from 12 per cent. to 3 per cent. in the course of two months.

In the month of March, 1848, the students and professors, including Clinical Assistant Semmelweis, were busy with the military affairs of the revolution, and the deliveries in the first clinic were left almost entirely to chance and the care of the head midwife. Under this policy of non-interference not a single death occurred in that month. During eight months of the previous year the mortality rate was as follows: In April and May of every 100 parturient women over 18 died, while in the following six months, after the careful washing of the hands of the students and professors with chlorine water had been enjoined, out of every 100 parturitions only 2.45 women died.

Semmelweis had promulgated the following assertions: "Puerperal fever must always be considered as a fever due to the absorption of decomposed animal, organic matter. This absorption may result from *auto*-infection (the product of infection coming from the individual herself) or from *hercto-infection* (the product of decomposition coming from without). Consequently not only the cadavers of every age and of every sex, when they are in a state of decomposition, but also the sick of every age and of every sex whose disease is accompanied by the decomposition of organic, animal matter, and, furthermore, every animal, organic tissue which presents a certain degree of decomposition—every one of these may be the starting point of puerperal fever."

This is unquestionably sound pathological doctrine. Had Semmelweis only had some knowledge of bacteriology his name would have been bracketed with those of Lord Lister and Pasteur. However, he deserves far more recognition for what he did than he has so far ever received, and doubtless time, which makes all things equal, will do justice to the reputation of a great and unselfish benefactor of the human race. Like all promulgators of a new and startling truth, he met with but scant appreciation when he first announced his discovery, and he had the misfortune to excite the enmity of his superior, Professor Kline, who had little sympathy for reformers, or even for investigators of any sort. This latter functionary prevented Semmelweis from obtaining a reappointment for two years as assistant to the Obstetric Clinic, a privilege which had been granted to his predecessor.

With the help of his satellites and the court favorites, both men and women, who had far too much influence at that time in medical affairs in Vienna, Kline proceeded to make Semmelweis' life in Vienna as intolerable as possible. They denied his assertions that by his method of prophylaxis the mortality rate in the Obstetric Clinic had been reduced fourfold, and when Semmelweis demanded access to the hospital records in proof of his statements they forbade him the use of the records.

Semmelweis then applied for the position of privat docent in obstetrics. After some vexatious delays this was granted him, but with certain humiliating conditions, probably intended to cause him to decline the position. When certain of Semmelweis's friends demanded the appointment of a commission to investigate the claims which he had made, the court party succeeded in preventing the investigation and began a counter attack upon Skoda, Semmelweis's principal champion, alleging that he entertained "materialistic opinions," whatever that may have meant. This contest waxed exceeding warm and the laity and the clergy, then as now quite ready to mix up in a quarrel, the bearings of which they could not comprehend, took a full part in the proceedings.

Semmelweis, whose native modesty had for a long time prevented him from accepting the invitation of the Vienna Medical Society to expound his views before them, finally apparently stung into action by the persecution to which he had been subjected, came before the society and set forth his claims with the proofs. He was exceedingly well received and was elected a member of the society. This was in 1850. Yet this partial triumph seemed to redouble the efforts of his enemies to drive him out of Vienna. Finally he yielded to the pressure, suddenly going back to his native town, Budapest, in Hungary.

So far as the advancement of his doctrine and the establishment of the truth of his great and beneficent discovery was concerned, his retreat from Vienna without even bidding his friends good-bye, was a bad move, as by so doing he alienated some excellent and powerful friends, including Skoda, whose energy and fearlessness had enabled him to triumph over the same stupid and malicious coterie that was persecuting Semmelweis. The sudden departure of the latter from the field of battle also gave the reactionaries an opportunity to say that there was nothing in his claims, or he would have remained at his post to defend them.

Some of the students of his life think that his sudden and ill-judged retreat from Vienna was due to an uncontrollable impulse and was an early manifestation of the mental malady which finally carried him into an insane asylum.

We have no time to follow this interesting man into his new field of labor, where his great learning and industry finally brought him sufficient recognition to secure him the chair of obstetrics in the local hospital, and where his abilities secured him a living practice. He wrote a book setting forth his theory and its proof. The latter part of the work, particularly, is burdened by long and ill-natured tirades against his enemies and those who refused to accept his doctrine, showing a gradual undermining of his crisp and vigorous intellect by the increasing mental alienation.

He gradually became more and more subject to alternating periods of mental exaltation and depression, and finally, in July, 1865, it was found necessary to take him to an insane asylum near Vienna. It was then ascertained that he had a gangrenous wound of one finger which had involved a joint and gradually extended up the arm, producing lymphangitis and adenitis; metastases formed and the disease finally assumed the form of pyopneumothorax, from which he died on August

13, 1865, within a fortnight after having left his home in Budapest.

It is a remarkable thing that he died of the disease which he had all his life fought so vigorously and finally succeeded in explaining so clearly. There was quite as much reason really for calling his fatal malady puerperal fever as for saying that the septicemia that carried off the patient of his friend Dr. Chiari in 1844, of which we have already spoken, was puerperal fever. An autopsy revealed the fact that Semmelweis had suffered from chronic degenerative changes in the brain and that those changes had been progressing for a considerable time.

While modern obstetrics and gynecology undoubtedly received their present great advance in antisepsis from surgery, especially from the epoch-making teaching of Lister, it is safe to say that if Semmelweis's teachings had been followed to their logical conclusions they would so far have revolutionized medical thought that surgery would have been indebted to midwifery instead of midwifery being indebted to surgery for the greatest advance ever made in the healing art, viz., asepsis. Curiously enough in this connection we note that in a report of Haller's on the work of the General Hospital in Vienna several pages are devoted to a discussion of Semmelweis's discovery, and the opinion is expressed that its bearing should be of inestimable importance to surgery. This was in the spring of 1849 and was probably the first time in the history of medicine that any suggestion had been made regarding the importance of observing prophylaxis, that is, asepsis, in surgical practice. As might have been expected, the solemn, conventional professors and teachers of surgery in the General Hospital smiled sarcastically at their colleague the *physician* who was so imprudent as to entertain any views upon surgical questions, and they treated his inspired suggestion with the same lofty disdain that Sinclair tells us the "unteachable obstetric mandarins of England" showed toward the first announcement of the great truths underlying the wound theory of the etiology of puerperal fever.

Semmelweis's great discovery was really no inspiration nor a revelation from heaven. It came, as nearly as all good things in science and education have come, to the trained and receptive mind of a faithful and painstaking worker in an especial field after years of study and careful thought. The death of his friend Kolletschka from an autopsy wound revealed the great truth to Semmelweis that the poor women in the first obstetric clinic were really dying of autopsy wounds. Semmelweis's interpretation of this phenomenon was as truly a scientific triumph as Newton's interpretation of the phenomenon of the falling apple. Both phenomena were common enough, yet in both cases it took a scientific intellect trained and directed by years of painstaking research to interpret the underlying causes correctly and thereby confer upon mankind inestimable and eternal benefits.

I cannot close this meager account of a most interesting personage without paying a tribute to his kind and manly heart. Had his pity not been stirred by the unfortunate women condemned to suffering and death while paying to nature the sacred debt of perpetuating their species, probably his great discovery would never have been made.

"Consider," says Carlyle, "how the beginning of all thought worth the name is love, and the wise head never yet was without the generous heart."

THE ETIOLOGY OF PROSTATIC HYPERTROPHY.

By EDGAR G. BALLENGER, M.D.,

ATLANTA, GA.,

LECTURER ON GENITOURINARY DISEASES, ATLANTA SCHOOL OF MEDICINE.

In order that the connection between the different parts of the paper may be clearer I will begin with a synopsis of my argument. None of the many alleged causes of the gradual progressive enlargement of the prostate gland in elderly men has been accepted as the true cause of this hypertrophy which occurs in about one-third of all men after 50 years of age (Thompson). This frequency implies that the cause is of very common occurrence. One of the first questions to ask is, "What can cause hypertrophy?" Adami says toxic irritation, small in amount and long continued, may cause overgrowth of the tissues subjected to such an irritant. The next question to suggest itself is, "Can a toxic irritant be found in the prostate glands of a sufficiently great number of men for it to be a possible cause of overgrowth in such a large percentage of elderly men?" The answer to this is yes. A mere glance through a microscope at preparations of the prostatic secretion, using the Reichert dark field illuminator, or stained so that the germs are seen actively motile, would be a much more convincing and also a startling answer, as millions of microorganisms can be seen, and this, too, from a prostate gland that is not inflamed; the largest number of germs being present when no pus cells are found in the secretion. These millions of bacteria have been demonstrated in the prostates of 110 patients during the past year, and finding them in so many patients with sexual neuroses, hyperesthesia of the deep urethra, occasional mild irritation of the bladder, itching of the urethra, "morning drop" discharges, etc., has done more to clear up these dark places in my work than any tests I have heretofore used. It is the enormous number of these nonpyogenic and almost nonpathogenic (excepting the hypertrophy) colon bacilli and staphylococci (occasionally other organisms) which I claim produce the mild persistent toxin which it is admitted by pathologists might cause hypertrophy.

Those who doubt my findings may easily verify them by a series of examinations of prostatic secretion obtained and stained according to the technique described later, or by the dark field illumination.

Many observers have noted the fact that from the pathologic standpoint the hypertrophied gland presents features characteristic of growths of inflammatory origin, and yet the histories often do not give the symptoms of inflammatory disturbances. They do, however, nearly always show the symptoms of these low grade infections. In carrying out these observations and studies I have attempted to verify the essential features of other work along this line, and to correlate them with my own findings, and I think the most convincing part is their complete accord with the clinical histories, bacteriologic and pathologic reports of a large number of careful workers in all of the different phases of this subject.

Among the alleged causes of prostatic hypertrophy nearly all of them are causative factors of the above-mentioned irritative infections (not inflammations). The study of bacteriuria and bacterial infections demonstrates how large is the number of

ways in which infections of the genitourinary tract may occur. Keyes says "bacteriuria is usually perpetuated by a renal or a prostatic lesion"; it is with the latter that this paper has chiefly to deal, although many phases of the character and sources of genitourinary infections will be discussed.

With this prostatic bacteriuria in mind the argument of my whole paper revolves around the following paragraph: Under the head of irritative overgrowth Adami says: "I have already dwelt upon the fact that substances which, in larger amounts and greater concentration, are toxic, leading to degeneration of tissues or arrest of function, often, in small amounts, act as direct stimuli to cells—and one of the effects of stimulation of the cells to increased activity may be increased growth." Whether the toxin leads to increased absorption and assimilation on its own part, or whether it produces a nutritional hypertrophy due to hyperemia, does not concern us in the present work, but rather the more important fact that toxic irritation, small in amount and long continued, can produce overgrowth of the tissues subjected to such an irritant. This being the opinion of Adami, a pathologist of the highest standing, my contention is that in the light of our present knowledge it does not seem unreasonable to assume that the toxins liberated by these mild germs cause the progressive chronic enlargement in elderly men. That there are other causes of prostatic enlargement, such as true adenomata, fibromata, myomata, carcinomata, and sarcomata, I readily admit. It also seems quite likely that the very small, hard, fibrous prostate is the result, at least at times, of a species of cicatricial change subsequent to very acute or destructive inflammation of the prostate. All of the above-mentioned enlargements are admittedly far less frequently encountered than is the ordinary form of prostatic hypertrophy.

I fully realize that the presence of these germs in the prostate gland even when enlarged does not prove that they cause the enlargement. Nor do I think direct proof or disproof possible. I have collected, therefore, as much collateral and circumstantial evidence as was possible with reasonable effort, hoping that I might at least enlist the assistance of other investigators whose reports and future observations might solve definitely this pathologic riddle and perhaps lead to its satisfactory prophylactic treatment.

History.—Home thought the cause of prostatic hypertrophy to be the slow return of blood from the neck of the bladder, with a habitual congestion of the part. Sir Astley Cooper believed enlargement of the prostate to be the consequence of age. Velpau, Paget, and Billroth thought the hypertrophy a true tumor formation (neoplasm). Brodie believed it a part of a general senile change. Thompson, and many writers in the early part of the nineteenth century, believed it to be of inflammatory origin. Guyon regarded it as merely a local manifestation of a disseminated arterial sclerosis or general atheroma. Reginald Harrison thought it the nature of a compensatory hypertrophy to overcome the primary depression of the floor of the bladder. Sir Charles Bell asserted that an irritation of the bladder with a frequent contraction of this viscus resulted in prostatic hypertrophy. Ammusat claimed that it is observed most frequently in elderly men who have for a long time used sounds or bougies upon themselves (Lydston). Desault found it very common in elderly men who had numerous attacks of gonorrhea. Lydston says, "A certain amount of diffuse hyperplasia from prolonged hyperemia incidental to various causes of irritation probably exists in many men under middle age."

Sir Henry Thompson found prostatic hypertrophy in 34 per cent. of men after 60 years of age, and that it produces manifest symptoms in about 15 or 16 per cent. of the cases in which it is enlarged. He thought it inflammatory. Virchow and Gouley believed that it was due to chronic inflammation which started in the glandular substance of the prostate. Wilson claims that strict celibacy, on the one hand, and venereal excess on the other are alike productive of hypertrophy, though admitting exceptional cases in persons living abstemious lives. The elder Gross laid great stress upon irritation and habitual engorgement as a cause of hypertrophy. Are not the majority of these observations in a way reconciled by the presence of the irritative infection of the prostate?

More recently Ciechanowsky reached the conclusion, from a study of pathologic histology of the enlarged prostate, that both the glandular and the fibrous overgrowths of the prostate are the long-delayed result of gonorrheal inflammation, insidious in onset, slow in course, and for many years, perhaps, entirely latent. Crandon, and Green, and Brooks have made similar studies, and reached the same conclusion.

In refuting Ciechanowsky's views, Keyes has collected the histories of a large number of patients who have had prolonged attacks of gonorrhea, but did not find that they showed any special tendency to prostatic hypertrophy. "This," he says, "taken in connection with the fact that every established genitourinary practitioner can call to mind many prostatics who he may be morally certain never had gonorrhea, seems to establish the fact that prostatic hypertrophy is not necessarily gonorrheal, but may be due to congestion of the sexual organs, to sexual excess or continence, to gonorrhea, or simply to advancing years."

Casper asserts that "neither the history of cases nor pathological investigation lends Ciechanowsky's theory support. In fact, the exact reverse is true. It is certain that there are men who have had gonorrhea and prostatitis for years without the production of prostatic hypertrophy, and conversely, he says, he has known many persons with enlarged prostates who never had gonorrhea." Adams says, "We know, however, that the process begins in the neighborhood of the glandular elements."

Pathological Histology.—Examination of a microscopical field from an enlarged prostate shows most noticeably, as a rule, increase in the glandular structure. Some have thought that new acini were formed, as in the case of the true adenomata observed in the mammary gland, where the chief pathological change evident is the preponderance of glandular tissues over the normally present fibrous reticulum; but in the prostrate the process does not appear to be one of true tumor formation, since the acini are merely dilated gland tubules which though previously present were then insignificant in size (Deaver).

Gouley says that the view of certain modern writers to regard chronic progressive enlargement of the prostate as a true adenoma is not in accord with our present definition of this term. Deaver asserts that "most recent writers have returned to the original view of an inflammatory cause and reject altogether the adenomatous theory." Deaver also says, "Nevertheless, practically every one is

agreed that there do exist two main pathological characters under which enlargement of the prostate gland is seen: one where there is a disproportionate increase in the glandular elements, and, second, where an increase in the stroma of the gland is conspicuous. In either case the increase may be local or general, or both processes may coexist, one exceeding the other in different parts of the same organ.

Young has observed from a study of sections of the prostate gland when inflamed that the "prostatitis is usually segmental in character, that it is most marked about certain groups of glands, and it is this which often produces the irregularity of the surface and nodular condition which is found on palpation." This being true of prostatitis, it would not seem unreasonable to assume a similar condition with different degrees of infection of various follicles would account for irregularities in the shape of the hypertrophied prostate.

Casper says, "Overgrowth of the glandular substance, however, is rare; it is usually destroyed, stroma being the portion which hypertrophies. I have, however, often seen considerable enlargement of the prostate as early in life as the middle, and even the beginning of the fourth decade." He thinks adenomata are very rare.

A form of prostatic obstruction may result from inflammation which differs from the progressive enlargement in that the former is of small size and is firm or fibrous in consistency. It contains none of the lobulations of the true hypertrophy (Young.)

Such prostates may result from active inflammation where the round cell infiltration becomes transformed into fibrous tissue before it is absorbed, or perhaps it may arise from a persistent subacute inflammation, which ultimately forms the fibrous prostate.

"No given example of hypertrophy adheres strictly to any one type; indeed, it is the rule to find all three types existing in different parts of the specimen: in one place a diffuse soft enlargement, in another dense masses of fibrous tissue, and scattered everywhere enucleable tumors, large and small, the larger ones complex in structure." (Keyes' last edition.) "These changes are due, as we have seen in the preceding paragraphs, to chronic interstitial fibrosis of the prostate; and however descriptive the terms adenoma and fibroma may be in this connection, we must remember that in using them we do not refer to true neoplasms, but to the pseudoneoplasms resulting from inflammation of the gland."

Organisms.—In my own work, as well as in nearly all of the reports and writings which I have consulted, there is a significant uniformity in the frequency with which colon bacilli and staphylococci are found in the genitourinary organs. In fact, so great is the preponderance of these organisms that all others sink into a relative insignificance.

The culture of thirty-one patients with subchronic prostatic inflammation grown for me by Dr. Edgar Paullin (to whom I am under many obligations for his skillful services in isolating and identifying these organisms) showed germs belonging to one or both of these groups in every instance. The *Staphylococcus albus* grew in the cultures of 14 patients; *Staphylococcus aureus* in 10; the colon bacillus in 10; *Staphylococcus citrius* in 1. The staphylococci alone were found in 15, colon bacilli alone in 9, and were mixed in 7; the *Staphylococcus aureus* and *albus* were found together in 6.

These observations are in accord with most of the work done by others in determining the kind of germs present in bacteriuria and genitourinary infections.

At times the colon bacilli appeared as cocci when first grown, and later assumed their usual form. This accounts for some of the motile cocci seen in the specimens. I think the motile colon bacilli also cause the staphylococci to seem to be moving when in reality they are knocked around by the myriads of colon bacilli.

Neither my own work nor that of most writers on this subject proves absolutely from the cultures that the germs which grow are from the prostate gland, as the urethra, especially the anterior portion, is always infected to a greater or less extent with a variety of organisms.

It is not, however, upon the cultures that I have depended to determine the presence of the millions of bacteria in the prostatic secretion, but upon microscopic preparations after thorough irrigation of the urethra and bladder, though cultures were made from thirty-one patients.

Cohn made cultures from twelve cases of prostatitis, using the following method: "Irrigate the outer urethra with boric acid till the fluid flows away clear; insert a sterile endoscopic tube in the urethra as far as the bulb; dry it with sterile cotton; massage the prostate gland; finally transfer the secretion from the tube to the culture by a platinum loop or a pleget of cotton." He found the *Staphylococcus albus* 11 times, streptococci 3 times, colon bacilli once and a Gram positive diplobacillus twice, and an unrecognized bacillus once.

Nottshaft grew cultures from 120 cases of chronic prostatitis which presented themselves from twelve to thirty years after the last gonorrhea, and besides the gonococcus he found micrococci 110 times, bacilli 15 times, and other bacteria 14 times. His technique was as follows: After the patient had urinated the urethra and bladder were irrigated with boric acid, then with physiological salt solution. The glans penis was "disinfected," then the prostate was massaged and the secretion caught, as it appeared at the meatus, in a sterile vessel. Both cultures and smears were made.

Saxe reported 150 cases of gonorrheal infections from six months' to eighteen years' duration. Of the 108 cases with prostatitis 28.7 per cent. showed gonococci in the prostatic secretion. Mixed infection was found in the prostate in 86 per cent. of the patients. Staphylococci, 74 per cent.; diplococci, 10 per cent., and streptococci in 7.6 per cent. Thirteen cases showed absolutely clear urine, although the smears showed prostatic infection.

As further proof that these infections often follow acute gonorrhea, I quote the following from Keyes: "The gonococcus alone, unaided by any predetermining cause, may excite an acute cystitis; in such cystitis the urine is acid and this purely gonorrheal cystitis recovers or is replaced by a secondary mixed infection so that the gonococci, if still present, can no longer be found. Hence, that striking clinical condition, acute gonorrheal cystitis, may be accepted as purely gonococcal in origin; while nearly all of the chronic manifestations in the bladder are due to secondary infection by the *Bacillus coli* and pyogenic cocci that everywhere follow in the wake of the gonococcus to perpetuate the inflammation inaugurated by it."

Posner says, "To-day it is recognized that with-

out any external interference and without any involvement of the neighboring organs urinary infection may occur." Anders asserts that there are probably few specimens of urine that do not contain bacteria. Reymond and Van Calcar believe the colon bacilli pass directly out of the rectum and into the bladder, where there is constipation or other intestinal obstruction.

Speaking of the prostatic type of bacteriuria, Keyes says, "there may or may not be prostatic hypertrophy." This would appear to show that he has seen it in hypertrophy. He says the distinction between pyelonephritic and prostatic bacteriuria may not be easy in a given case. "Indeed, the two may doubtless coexist. Yet an alkaline bacteriuria is almost invariably prostatic; a bacteriuria following gonorrhea or due to instrumentation or to stricture is probably prostatic. A bacteriuria occurring during the course of a prostatitis or of a prostatic hypertrophy is doubtless prostatic. Finally, the expressed prostatic secretion after urethral and vesical irrigation will be found to contain the incriminated bacteria in great number if the bacteriuria is prostatic."

Corner has had the urethral discharges examined in fifty cases, and found gonococci in 46 per cent., and other organisms in 54 per cent. Among the latter colon bacilli and staphylococci were found to predominate.

In discussing bacteriuria Geraghty says, "It is well known that both the *Staphylococcus albus* and the *Bacillus coli communis* may have little or no pathogenicity, and this explains to a certain extent why the growth and persistence in the urinary tract (of the germs) occur without producing inflammatory phenomena."

Whiteside, emphasizing the importance of nonvenereal infections of the urinary tract other than tuberculous, has recently asserted that nonspecific infections are more common than is generally supposed, and that the severity of the symptoms ranges all the way from the very transitory irritations to chronic cystitis. In many of these he has found that the "colon bacillus is the infecting germ; in others the *Staphylococcus albus*, the pneumococcus, and a short square ended bacillus may be found in pure culture, or sometimes two or more kinds together." Young says, "it seems probable that multiple infection is not uncommon." Chute has collected and reported cases of alkaline bacteriuria and mild infections due to *Staphylococcus pyogenes albus*. In these no ammonical decomposition occurred. Gassman reported a case of cocciuria associated with seminal vesiculitis and double epididymitis. Krogius reported two cases of bacteriuria with a prostatitis as a probable cause, and Goldberg one such case accompanying seminal vesiculitis. Young remarks many surgeons can recall similar instances in their work.

In the fifth annual report of the Henry Phipps Institute it is recorded that in 185 kidneys which were examined bacteriologically and cultures grown microorganisms were found in 82, while none were found in 103—streptococci, 28 per cent.; *Staphylococcus aureus*, 8.5 per cent.; *Bacterium coli commune*, 48.8 per cent.—(this last was the most common during the last year, being found 11 times out of 20 positive cultures, total number being examined, 62).

Typhoid bacteriuria occurs in from 15 to 30 per cent. of all cases of typhoid fever, and while the bacilli usually spontaneously disappear from the urine they may remain for years. The urine is acid and closely resembles that of bacillus coli bacteriuria (Keyes).

In discussing Rovsing's view that colon bacilli never cause cystitis, Keyes says, "Numerous attested cases of cystitis prove it (the colon bacillus) is not always as innocent as Rovsing believes—(Keyes records in a footnote 'these usually originate from a bacillus coli prostatitis') while the increasing number of reported cases of bacteriuria containing bacillus coli in pure culture show that its venom has been overestimated in the opposite camp." (Melchoir and Albarran and Halle, who assailed Rovsing's position.)

Bacteriuria was first described in 1881 by Roberts; since then, an increasing number of observations have been reported and the condition studied by many workers, especially Rovsing, Krogius, Janet, Jeanbrau, Geraghty, and others have recognized its not infrequent occurrence. The term bacteriuria is limited to conditions characterized by the presence of enormous numbers of bacteria in the freshly voided urine without any pronounced symptoms of inflammation of the urinary tract. Rovsing has observed two types of the affection, one in which the urine is absolutely free from pus, another in which a few pus cells are present, but the peculiar cloudiness of the urine is due to bacteria. The writer has distinguished these two types both in the prostatic infections and in renal or bladder bacteriuria.

Of bacteriuria Casper says, "Many of the organisms are merely excreted in the urine, having their origin in the distant parts of the body and pass through the kidneys into the bladder without causing disease of the latter organ." Fresh normal urine is sterile.

For a number of years I have observed patients with sexual hyperesthesia, or the so-called sexual neuroses, without demonstrable lesions to account for the persistence of the symptoms. Rarely did smears of the prostatic secretion show sufficient organisms to lead me to believe the germs to be the cause of the trouble. In studying the prostatic secretion of these patients, however, with the Reichert dark field illuminator, my attention was at once strikingly focussed upon the large number of motile organisms frequently seen in specimens free from pus cells. Later I found that a drop of this discharge, mixed with a 1 per cent. aqueous solution of dahlia, over which was placed a cover glass, enabled me to see more readily these actively motile organisms. Since that time about 140 patients have been examined in this manner to determine if there was a bacteriuria or prostatic infection. In the present report I have not included the patients where pus was present except in small amounts, as such cases come under the heading of the inflammatory conditions, which are much better understood than are these "subchronic" infections.

In 110 patients with very mild genitourinary irritation or slight affections of the sexual organs, a large number of mildly pathogenic organisms were observed in the prostate gland, seminal vesicles, or in the urine. Cultures of thirty-one of these showed the germs to belong to the colon bacillus group, or to the staphylococcus group. A surprisingly uniform and well-defined symptom complex was found to attend these infections.

Etiology.—Usually the origin or at least a possible source of the infection could be found in the past history of the patient. Gonorrheal urethritis and instrumentation seemed to be the most likely and the most frequent of the possible causes.

Probably three-fourths of the patients gave a

history of acute inflammation of the urethra which had been apparently cured, or almost cured, and yet at times a little irritation would develop at the neck of the bladder at more or less frequent intervals, and lead the patient to believe that he was uncured, and about to have a recrudescence of the original gonorrhea. Not infrequently there was a history of the passage of sounds for a considerable period of time, and often with temporary relief of the "uneasy" feeling in the urethra. (Of course, urethral strictures have been excluded from this report.) Very frequently there were evidences of rectal or anal lesions such as hemorrhoids, fissures, fistulæ, ulcerations, pruritus ani, etc. Ten patients with enormous numbers of these mildly pathogenic organisms in the prostate gave no history of urethral inflammation of any kind or of urethral instrumentation, but they all admitted having indulged to excess in masturbation, prolonged ungratified sexual excitement, or having remained continent for a prolonged time.

Anything which produces a continued congestion of the genital organs seems to act as a causative factor, and to favor the development of prostatic and vesicular infection. Rovsing has reported 285 cases of colon bacillus infections of the urinary passages; in 180 the disease arose as an acute nephritis or hydronephrosis in patients who had never been catheterized. He believes that in many cases the colon bacillus reached the urinary organs through the blood stream, and that some of the starting points were tonsillitis, cholecystitis, acute enteritis, appendicitis, colitis, cancer of the colon, and typhoid fever.

Fuller, speaking of colon bacilli in the chronic inflammations of the seminal vesicles, says they are to be expected in nearly all such cases. "A seminal vesicle which long remains pathologic from any primary cause can hardly escape colon bacillus infection, owing to its position in close opposition to the rectal wall." The same probably is true of the chronically congested prostate gland, and this probability is greatly increased if we bear in mind the additional danger of infection from the urine, from kidneys diseased as those reported by Rovsing, or from organisms of hemotogenous origin passing through healthy kidneys.

With all of these possible sources of infection one hesitates to express an opinion as to which is actually the most frequent one. Raymond and Van Calcar go even further and claim that colon bacilli pass directly through the rectal wall into the bladder when there is constipation, or rather, intestinal obstruction.

Symptoms.—The symptoms are usually those of a very mild urethritis, with a little irritation at the neck of the bladder, and mild symptoms sometimes referred from this region. A very common symptom is itching in the urethra, not severe, as a rule, but often returning without any apparent reason. The patients also frequently complained of a sensation as if discharge were escaping from the urethra, and yet upon examination no discharge would be found. Occasionally sharp, fleeting pains were observed in the urethra, penis, or prostate. A "morning drop" of mucus or mucopus was found in some of the patients, while in others it was persistently absent.

Well marked sexual impotence was found in 10 out of the 110 patients; about 72 experienced premature ejaculation, and a few complained of pain, or burning, in the deep urethra during the orgasm or immediately after its occurrence.

Mild rheumatism, involving the knee, hip, shoulder, wrist, ankle, and other joints, was observed in 25 patients. The rheumatism was characterized by its mildness and persistency, being amenable to no ordinary form of antirheumatic treatment. Slight pain, or aching in the lower part of the back, was of frequent occurrence, and was of the character often seen in chronic prostatitis.

The conditions I have previously considered sexual neuroses and hyperesthesia, where the disturbance was all out of proportion to the inflammatory products, have in every instance shown the prostate to be infected with these mild organisms.

In 69 of the patients the urine showed a few mucous shreds; in 20 it was macroscopically clear, but at times it would become slightly cloudy, or opalescent, resembling urine in which there is a slight precipitation of phosphates. This cloudiness was due to microorganisms which at times caused the urine to have an unusually disagreeable odor, especially if it was allowed to stand for any length of time. A number of observers have found that bacteriuria due to colon bacilli produces an acid urine, but when due to staphylococci it is likely to be alkaline. This, as a rule, has been confirmed, but exceptions are not unusual. Neither filtration nor centrifugation will clear the urine of this cloudiness.

The size of the prostate gland seemed to vary in size almost always directly in proportion to duration of the infection in the patients where a definite history could be obtained as to the approximate date of the infection. In some patients it was impossible to estimate the duration of the trouble. The age of the patients was from 19 to 65; nearly all of the older ones showed distinct increase in size, while several patients between 40 and 65, with well-marked hypertrophy, but free from pus infections, showed large numbers of germs, although the urine was macroscopically clear. I have not yet seen a patient with an uninflamed hypertrophied gland from which the secretion did not show an infection. Unfortunately, many of the patients with well-developed hypertrophy had pyogenic infection with true inflammation of the bladder urethra or bladder, and were thus excluded from the class of patients included in this report, as these changes are secondary to the hypertrophy. It is from the beginning enlargement rather than from the fully developed cases that our studies of the etiology will be productive of results. Where there was not a distinct enlargement, as in the older men examined, there was generally a sensation of firmness rather than of "bogginess" or "congestion" observed in chronic inflammations; others appeared to be of normal size, and some even smaller than usual. The patients nearly always complained of undue tenderness of the glands during the massage. The secretion, as a rule, was rather small in amount and looked much like diluted milk. A peculiar feature was that the large acutely inflamed glands, as a rule, showed very few germs and in the secretion from chronic inflammation the organisms rarely were as numerous in that which was free from pus. While this was almost always true of the prostate, it was variable in the urethral and bladder inflammations, as here sometimes millions of organisms were present with much pus.

One of the most significant cases was a patient, 29 years of age, with epispadias, the entire roof of the urethra being deficient. The prostate was about

three times the normal size and reeking with millions of germs, but no pus was present. A glance at the fertile soil afforded by the urethra and moist mucosa was sufficient to convince one that the deeper parts must of necessity have been infected in childhood or early youth if not during infancy. No other cause could be found which seemed to have any bearing upon the hypertrophy of the prostate in this case.

Technique.—An irrigation of the urethra and bladder is given according to the Janet-Valentine method with a normal saline solution until one to two quarts of the solution has been used. Having the bladder partly filled with the irrigating fluid, the prostrate is then massaged and a drop of the secretion which appears at the meatus is placed on a slide; a drop of a freshly prepared 1 per cent. aqueous solution dahlia is mixed with this drop of secretion. A cover glass then placed over it is sealed in place by applying melted white wax or paraffin around its rim with a camel's hair brush. As a confusing precipitate forms at times, and especially when the specimen contains urine, it should be placed under the lens of the microscope and allowed to remain in this position for 15 or 20 minutes or longer, to allow the precipitate to settle to the bottom and become quiet, otherwise the Brownian movement of these minute bodies might be mistaken for motile organisms.

The germs remain motile for a few days to a week, and a positive diagnosis may be easily made by a series of subsequent examinations, when their motility differentiates them from the débris which settles and becomes motionless. If preferred, the specimen may be viewed with the dark field illumination and the diagnosis thus made. Fixed smears may also be made and stained in the usual manner, but these rarely give as accurate an idea of the presence of microorganisms as does the above method.

THE ANTI-TUBERCULOSIS PROPAGANDA.*

By JOHN B. HUBER, A.M., M.D.,

NEW YORK.

PROFESSOR OF PULMONARY DISEASES FORDHAM UNIVERSITY MEDICAL SCHOOL; MEDICAL EXPERT N. Y. STATE DEPARTMENT OF HEALTH; VISITING PHYSICIAN ST. JOSEPH'S HOME FOR CONSUMPTIVES; EXAMINER THE WHITE HAVEN SANATORIUM, ETC.

We shall get much inspiration and encouragement in this crusade if we consider the tuberculosis situation before and since Koch's epochal discovery in 1882.

Tuberculosis, or consumption, is probably as old a disease as the human race. At any rate, more than twenty centuries ago Hippocrates, the father of medicine, spoke of it as the disease which caused the most suffering and the greatest number of deaths. And since his time, throughout the ages, consumption has ever been the greatest destroyer of mankind. Such diseases as smallpox, cholera and the bubonic plague have never been in the running with consumption. During the nineteenth century 14,000,000 died in wars, either through camp disease or by the bullet and the sword; while in that century at least 30,000,000 succumbed to consumption.

Up to our own time one death in seven from infancy and old age has on the average been due to tuberculosis, while between the ages of fifteen and forty-five one-third to one-fourth, and sometimes one-half of all lives have been sacrificed. Think of this: Between the fifteenth and forty-fifth years, the years when young men and women are entitled to look forward to marriage, between those years when men should be strong to work for and maintain their families, when wives should be strong to rear and bring up their children, when you and I should be strong to do the world's work—every third or fourth among us has succumbed to the great white plague. And among our negro brethren every other adult has died of consumption, though this unfortunate race never knew anything about the disease until we benevolent whites decided to confer upon it the blessings of civilization. Our Indian wards—what irony does the term convey?—have been dying off in greater numbers than the negro, and in much greater number than our white population—so states the Bureau of the Census in Washington. Like the negro, the Indian never knew consumption before our blessed advent; neither did he know the curse of rum; and now our tubercle bacillus and our fire water are fast wiping that once splendid race of men off the surface of the earth.

Among the various occupations in which our people are employed tuberculosis has been claiming from 38 to 87 per cent. The yearly consumption mortality in the United States has averaged 140,000.

Nor do these figures connote the many months and years of sickness endured by those who have recovered from their disease. Nor do they connote the anguish and suffering endured by the families of the consumptive (who is so oftentimes the wage earner); what the husband, the wife or the children of the consumptive have to endure in these dreadful circumstances. Consider the matter also on a purely cash basis. Dr. Porter, our Commissioner of Health, states that the disease has yearly been cost-

*Address in a mass meeting at Niagara Falls, N. Y., under the auspices of the State Department of Health and the State Charities Aid Association.

ing the people of our State $70,000,000, while Prof. Fisher of Yale—one of those men who have recovered from consumption, and who are now so nobly fighting the disease in behalf of their fellows—has found that tuberculosis has annually been costing the United States more than a thousand millions of dollars.

Such has tuberculosis been in the past. But a new era dawned when Pasteur demonstrated to the world the germ origin of infectious diseases; it was this great man who encouraged the world with the scientific statement that it is within human power to banish all parasitic diseases from the face of the earth. Soon thereupon in 1882 came the discovery of the essential cause of consumption, the tubercle bacillus, by Koch. And thus was established a sure and logical basis for the fight against this age-long scourge. And upon the foundation thus laid by Pasteur and Koch, Bodington, Brehmer, Trudeau and hundreds of other devoted colleagues have worked—and with what result?

In Koch's own Prussia the terrible mortalities of the past have been cut down 40 per cent.; in Boston nearly 50 per cent.; in New York City 50 per cent. From the reports of Mr. Frederick Hoffman, the statistician, we gather that between the years 1901-1906 tuberculosis decreased 20 per cent. in our Northern cities. In England there is a noble worker, Bulstrode, who well defined the object of preventive medicine to be "to curtail, and, if possible, to prevent, disease, to prolong existence, and to render life happier by means of improved physical conditions." Recently Bullstrode declared that if the tuberculosis mortality should continue to decrease in England and Wales in the ratio that has obtained during thirty years past, consumption should disappear totally within those borders within the coming three or four decades. Flick of Philadelphia, another lifelong and earnest worker (himself once a consumptive), has expressed the judgment that if the anti-tuberculosis propaganda on which we are now engaged gathers normal and natural force as it progresses, the disease should in from fifteen to twenty years be stamped out in all the large centers of our population.

Now, I, for my part, do not expect such results so soon; however, let us but recognize that a fight half won is already won; that we have already half won this fight, and we can safely leave the element of time to take care of itself. And this I do believe: that, if we continue faithful in our efforts, our little children before they have grown to maturity will find tuberculosis bereft of many of its age-long terrors; that before they in their turn are a-graying, they will recall tuberculosis as we now think of smallpox. There is a legend raised in this hall—*No tuberculosis after 1930;* did crusader ever raise a more inspiring banner under which to fight?

And now I put this to you: Before the beneficent discovery of Jenner smallpox devastated whole cities, and wiped whole towns and villages out of existence. Every other man or woman one met on the thoroughfare was a pock-marked survivor. If any one had said in those days that smallpox would be eliminated from human experience, he would have been considered unfit to be at large. Yet today who among you know of a case of smallpox? And it would be easier to eradicate consumption than it has been to eradicate smallpox, for this reason: that the tubercle bacillus cannot thrive (except under laboratory conditions) outside the living body. So that the ultimate extinction of tuberculosis will rest simply upon the destruction of this germ before it can be transferred from the consumptive to the healthy individual; and such destruction is, in theory, and should be in fact, one of the simplest processes in disease prevention. "No spit, no consumption"—this is a wonderfully good working motto, though it does not, of course, tell the whole of the story.

How have these wonderful results been brought about? And upon whom do we confidently base our hopes for the future? Not by the doctors alone; not upon them alone. Tuberculosis, let me assure you, is not only a doctor's affair; it is, or should be, the intimate business of every man, woman, and child in the State and nation. You see that, besides being a disease, tuberculosis is also a most baneful sociological and economic factor.

Medical science has been, since Pasteur and Koch, the pillar of fire to lighten the way; but we have progressed so far because all sorts and conditions of men and women have worked with the doctor in the introduction of tuberculosis prevention, which means practical sanitation, into every phase of our infinitely complex civilization. And the campaign against consumption is one against disease in general; don't lose sight of that. The individual as husband, wife, and child, teacher, nurse, tradesman, laborer, artisan, builder, statesman, humanitarian, and churchman; humanity as organized in lodges, leagues, societies, and associations, have all and are now most loyally, with the doctor, putting the shoulder to the wheel—with the superb results we have considered.

Among the many factors by which we are winning this fight against consumption I would mention here especially the notification and registration of cases, which measure should have the heartiest support of all good citizens; the diagnosis of cases in the incipient stage, so that the sufferer may be cured of his disease; the removal of adenoids and unhealthy tonsils from children, so that they shall not become predisposed in adolescence to tuberculosis. Then there is the vital factor of tenement house and sweatshop reform; most vital by reason that tuberculosis is preeminently not a hereditary or a family disease, but a *house* disease. Then dispensaries (with visiting nurses) and sanatoriums should be established. Hospitals for advanced cases are an inexorable need; for the poor and most unhappy consumptive, in his last days, so weak oftentimes that he cannot raise the sputum cup to his lips, is a dreadful distributor of infection, not only in his family, but in his neighborhood as well. There is now a most beneficent law by which, after a hearing by the Commissioner of Health of the State and the local health office, such hospital may be established in any community. Every citizen should further this good law to his utmost ability. Far from being a menace, these hospitals are the community's greatest possible safeguard against the Great White Plague.

Finally there is education, such as you see exemplified in this magnificent exposition which now surrounds us, and which has been made possible by the union of governmental with non-governmental forces, by the cooperation of State Charities Aid Association and State Department of Health.

And now I shall ask you to consider the legend which adorns the pavilion which our labor bodies have enacted in Albany for tuberculosis sufferers: "This is organized labor's contribution to the anti-tuberculosis propaganda. *What's yours?*"

ACUTE INFLAMMATIONS OF THE MIDDLE EAR AND THEIR TREATMENT.*

By M. D. LEDERMAN, M.D.,

NEW YORK,

ATTENDING AURIST AND LARYNGOLOGIST, LEBANON HOSPITAL; CLINICAL PROFESSOR DISEASES OF THE NOSE AND THROAT, N. Y. POLYCLINIC.

When asked to present a paper before your Association at rather short notice, I decided to offer a few remarks upon acute inflammatory affections of the middle ear, and their treatment. Before considering the subject from a therapeutic aspect, permit me to call your attention to some of the etiological factors frequently associated with aural disease.

Among the contributing causes influencing the organ of hearing are (*a*) anatomical or mechanical, (*b*) pathological, and (*c*) constitutional. As an illustration of division (*a*), I would mention congenital narrowing or malformation of any portion of the bony auditory apparatus itself, or of the nasal cavity. Membraneous or osseous obstruction of one or both nasal cavities is not common, but does occur. Absence of proper atmospheric pressure under such conditions induces circulatory changes. Tubal engorgement and obstruction soon retard normal ventilation of the middle ear and a disturbed ratio of atmospheric pressure results.

It is not my intention to describe the anatomy or physiology of the Eustachian tube and its surrounding structures. We must learn, however, to appreciate the importance of normal nasal respiration and its bearing upon auditory function. When we inspire, there is a partial vacuum created in the nasal cavity which is followed by an increased air pressure at expiration. This alternating rythm causes an interchange of air in the nose and adjacent spaces. Any condition interfering with or retarding this physiological ventilation predisposes the surrounding tissue to circulatory disturbances. We may here briefly consider the most prominent factors in the production of catarrhal diseases of the Eustachian tube, and the tympanic cavity.

Pathological changes in the nose, nasopharynx, and faucial region are the direct cause of the greater number of such affections. Nasal obstruction, due either to repeated colds in the head, enlarged turbinals, septal spurs, ethmoidal disease, or adenoid growths, causes a diminished atmospheric volume in the postnasal space or epipharynx. This negative pressure permits an engorgement of the mucous membrane which interferes with the natural action of the Eustachian tube, thus retarding normal middle ear inflation. Repeated coryzas or earaches in children should direct our attention to the possible presence of postnasal irritation. An aural examination will reveal the retracted or sunken drum, demonstrating the absence of adequate ventilation.

The infectious diseases of childhood and their associated respiratory complications are active causes in the primary or secondary infection of the middle ear. Especially is this true when some nasal or pharyngeal ailment previously exists. Enlargement of the faucial tonsils predisposes the individual to infections in the gland, which may be the starting point of a serious otitis. This may occur either through the Eustachian tube or by secondary involvment from the lymph channels. The careless use of the douche in obstructive diseases of the nose and the faulty use of the handkerchief are also causes of acute inflammations of the tympanic cavity. It is surprising how many persons employ this necessary article improperly. In clearing these spaces, one side of the nose should always remain free, so that the increased air current can find a ready exit. If both nostrils are occluded at the same time, the increased pressure finds the path of least resistance at the Eustachian opening and may carry infected secretion through this passage.

Constitutional causes may act in a primary manner but usually start their influence through the circulatory system. Lithemia produces a sensitive mucous membrane susceptible to barometric and digestive disturbances. Syphilis as a rule attacks the internal ear, and is characterized by abrupt and profound deafness. The tuning fork shows nerve involvment. Tuberculosis is rarely acute and is not accompanied by pain. In these specific infections, the modern pathological laboratory will promptly assist in establishing a diagnosis.

Acute otitis media is most frequently due to some form of infection, finding an entrance through the Eustachian tube. It is generally preceded by an acute process in the fauces and nasopharynx, which also involves the Eustachian canal. Examination will find the nasal tissues catharrhal and swollen. Postnasal inspection demonstrates an acute inflammation of the mucous membrane, with more or less occlusion of the Eustachian opening. Secretion is frequently observed lodged in the mouth of the tube. Coughing or sneezing may force the exudation into the canal and incite infection.

The attack usually appears with a feeling of fulness in the affected ear, accompanied by a dull ache, which increases during the act of swallowing. Some elevation of temperature may be present, and at times a chilly sensation is experienced. In children the temperature is usually high and constitutional symptoms are more marked. In cases of moderate severity the congestion of the drum is limited to its upper portion (Shrapnell's membrane). If the inflammation is more active, the entire membrane will be reddened, and may become so swollen that all landmarks are eliminated. In the influenza type small vesicles appear on the drum and canal and are characteristic of this disease; tinnitus is not always present. When considerable exudation exists, there will be some bulging of the tympanic membrane. Pain may be of a neuralgic type, involving the teeth and face.

Treatment of acute catarrhal otitis media should be started by an active saline laxative. If any elevation of temperature is present, absolute rest in bed for a day or two will assist in bringing about a good result. For the relief of pain, heat seems to be the most efficacious remedy. It may be applied in dry or moist form. The salt, sand, and hot water bags, Japanese hot box, or heated hop rag are well known methods. In the use of the douche, we shall get better effects by combining with it the glass return flow apparatus of Lucae, or Fowler's automatic suction attachment. The latter is especially serviceable when suppuration exists, and continuous drainage is desired.

The higher the temperature the irrigating solution can be borne with comfort by the patient the better the result. We must be careful not to parboil the auricle, however; ordinarily a temperature of 110° to 120° will feel very soothing to an adult with a throbbing ear. In children the temperature should be about 105° to 108°; a quart of physiological saline solution should be used with the douche every two hours, while the patient is awake. If the pain per-

*Read before the Society of Alumni of Lebanon Hospital, December 7, 1909.

sist in the interim, a few drops of a ten per cent. carbolized glycerin may be introduced into the external canal after each douching. In children a five per cent. is sufficiently strong. Continuous heat may be applied by salt or hot water bag after the drops are instilled. A mixture of cocaine, menthol and carbolic acid has also been recommended for the relief of pain, to be similarly employed. The latter is also used as a local anesthetic when myringotomy is indicated, though nitrous oxide anesthesia is much more satisfactory to both patient and operator. When bulging of the drum appears we must assist nature by opening through its most prominent portion. A free incision should be made, otherwise good drainage will not follow. To avoid the introduction of infection it is necessary to cleanse the canal with pure alcohol or other antiseptic solution, before incising the drumhead. Douching the ear may then be continued as before mentioned.

Bier's hyperemic treatment has been employed as a prophylactic measure in cases of acute otitis media and when mastoid symptoms exist. Professor Eschweiler of Bonn claims that prompt application of the elastic band to the neck immediately after the onset of the otitis may often control the disease and prevent further complications. If an abscess has already formed this must be incised, and suction is applied in conjunction with the neck constriction.

Treatment to the nose and nasopharynx is important. The congested mucous membrane should be reduced by applications of weak adrenalin solutions. All secretion must be removed, and then gentle inflation with the Politzer bag should be attempted. If the parts are very sensitive, it is advisable to wait until the active acute symptoms have subsided before using inflation. To protect the sound ear during inflation with the bag, the patient should place the finger tip into the external meatus. If the auscultation tube is employed with the Politzer bag or when the catheter is in position, the presence of secretion in the Eustachian canal or middle ear can be detected. Instead of a blowing sound, râles will be heard. At times it is possible to see fluid through the drum, after the initial congestion has disappeared. A line may be seen extending across the membrane. The level of the fluid is disturbed by changing the position of the patient's head. After inflation, bubbles may be seen in the tympanic cavity, the fluid having been spread by the air pressure.

In a young woman under my care this method had no effect upon the residual secretion. She experienced considerable discomfort on account of the existing deafnes, and an annoying fulness which persisted, but did not complain of any pain. There was no elevation of temperature. On inspection the fluid could be readily seen behind the drum. After cleansing the external canal in the usual manner, an incision was made along the lower segment of the membrane but no fluid appeared. The catheter was then used and a mucoid secretion of gelatinous consistency popped through the incision. At once the unpleasant symptoms were relieved.

It is important to continue tympanic inflation for some time after active signs have passed, in order to prevent adhesions from forming. We can assist the natural drainage of the middle ear by keeping the Eustachian tube patent. Applications of weak silver nitrate (1 to 2 per cent.) and stronger organic silver (30 per cent.) solutions, through the nose to the pharyngeal orifice of the tube, and postnasal applications of the same remedies, act very nicely in catarrhal cases. A one per cent. camphomenthol benzoinol spray for the nose is of value for its local effect. Aural massage may be resorted to later on. It is not to be used until inflammatory symptoms have disappeared. With a combination of the Delstanche masseur and the Siegle otoscope the effect upon the tympanic membrane is constantly observed, and unpleasant consequences can be avoided. Severe pain and vertigo may follow the too strenuous application of this instrument. In subacute cases where tubal symptoms persist I usually introduce through a sterilized catheter a few drops of a one per cent. camphomenthol benzoinol solution. In chronic cases iodine is added to the mixture.

The symptoms of an acute purulent otitis are similar to those of the catarrhal type, only greater in their constitutional effect. Many such cases start as a catarrhal condition and terminate in pus formation. When the disease is purulent from the beginning the temperature is high, a chill may have ushered in the attack, and the aural pain is severe and continuous. Children show considerable nervous disturbance and convulsions may occur. The eruptive and infectious diseases are active factors in the production of severe purulent disease in the middle ear.

In young children the presence of pus in the external canal or on the pillar is often the first manifestation noticed by the mother. Examination of the ear shows a congested and swollen drum, with probable bulging. Sagging of the posterosuperior portion of the auditory canal indicates invasion of the mastoid antrum and anterior cells. Prompt drainage should be performed along the posterior portion of the drum and carried upward into the attic.

Hot antiseptic douching should be regularly employed, and a bacteriological examination made of the discharge. All severe infections of the middle ear may cause tenderness by pressure over the mastoid antrum. When we consider that this cavity is merely a continuation of the tympanic cavity and lined by the same mucous membrane, it is natural that congestion will occur at this site also. Consequently tenderness over this region is frequently present. If in spite of free drainage and hot irrigations this symptom persists, together with sagging of the posterosuperior canal wall previously mentioned, and streptococcus infection, one should not hesitate to open the mastoid cells.

Suppurative otitis resulting from scarlet fever, influenza, and other infectious diseases are usually severe and extend rapidly. Early drainage of the middle ear is important to prevent destruction of tissue and further complications. We must not overlook the possible involvement of cranial tissues during an acute process. Cases of labyrnthine involvment are recorded during the course of typhoid and other infections.

When secretions are thick, alkaline solutions for douching should be employed. Peroxide of hydrogen is of service in dissolving the tenacious discharge. It should not be used where drainage is retarded. Irrigations with formalin solutions one to one thousand act favorably, after the acute period is passed. Inflation of the middle ear must be carried out to prevent adhesions from forming.

Rest, early drainage, and attention to the nasal and postnasal factors are the cardinal features in the treatment of acute otitic inflammation.

58 East Seventy-fifth Street.

HOSPITAL NOISE.

By H. A. BOYCE, M.D.,
KINGSTON, ONTARIO.
SUPERINTENDENT KINGSTON GENERAL HOSPITAL.

Before proceeding to discuss this subject of "Noise" it is desirable that we should know exactly what is implied. The Standard Dictionary defines it as a sound of any kind, but especially one of a disagreeable nature. My attention was forcibly called to this subject by an incident reported by a leading specialist of one of the cities of Ontario who had just returned from London. While visiting one of the homes for the nervous in that city he said he was much impressed by the almost absolute silence of the place. What impressed him most was the whispering tones in which his questions were answered by those accompanying him and by a courteous request to modulate his own voice. "Surely," thought the doctor, "this is an ideal atmosphere for nervous patients." But why is it not essential for the best results in the treatment of any type of disease.

"My," I thought, "how different are the conditions subsisting in our hospitals, although 'silence' as a printed word may be prominent upon our door posts and lintels it enjoins a law honored more in the breech than in the observance."

Have you not heard the slamming of the door and the doctor's stentorian "good morning," the stumbling of the visitor as he slowly mounts the stair, the laughing chatter of some idiotic house surgeon or sillier nurse, the moaning of the operative, the crying of children, the whistling of the staff, and the thousand other noises which may be within our walls. But let us ask ourselves the question do we really hear them or have we become so accustomed to the commotion that it goes on all unnoticed. It seems to me we are much like the inhabitants of that Scottish city in which the incessant noise of steam hammers and the clangor from boiler plates created a din deafening to the unaccustomed ear of the visitor but so natural to the natives that when some accident resulted one night in the closing down of the machinery, the sudden quietness produced, every sleeper awoke to find out "what the racket was."

The fact is we have never seriously considered the matter. I am free to confess that is true in my own case. Judging from the little I could find written on this subject, I think it is one that has been neglected both in theory and practice. At first sight it may seem too trivial to merit serious consideration, but I am convinced after due thought you will agree with me that it is of paramount importance and that the abolition of every unnecessary noise is a crying need in every institution for the care of the sick. If the whole number of superintendents had suddenly to change places with the patients and betake themselves to their cots how long would it be before there would be a revolution?

Imagine a patient from the London Home described by our specialist friend transferred to the conditions I have described, would he not say to himself, exist rest—enter pandemonium.

Let us consider for a moment the case of the pneumonic nearing the crisis or the gasping victim of myocarditis. We all know that every thought as well as every act requires a definite expenditure of vital energy. This expenditure seems directly proportional to the unpleasant content of the thought or act. We, who are well, know the drain felt after a day in which have occurred three or four irritating or annoying experiences. If we, then, feel such drain how ill can these weak ones bear the waste of the irritation to which they are subjected. Can you not recollect cases in which the balance easily turned was moved against such a one by some of the preventable disturbances we have mentioned.

Have I overdrawn the picture of conditions subsisting in our hospitals on this side of the Atlantic? I hear some say this does not describe things as they are with us. We hope many can honestly so affirm, but even to these dissenting ones is the consideration of this subject waste time? Can we not all see many ways this disturbing factor "Noise" is preventing the realization of the highest efficiency in our hospitals? I wish I could leave this paper with these broad generalities as it is. I think the representatives from Canadian and United States hospitals would acknowledge that it contained material for personal application. It is not a sermon that each can apply cheerfully to the other fellow.

A friend of mine who was a patient in one of the largest hospitals in one of the largest cities of this continent, an hospital that deservedly enjoys a continental reputation, told me that its associations to her would always be crystallized in its personification of not only perpetual motion, but noisy perpetual motion. When this is the impression given by one of the best institutions what would be that made by the rank and file.

But you may say, how is all this to be remedied? This brings me to a phase of the subject I would gladly escape trying to deal with. Gladstone is said to have always held the breathless interest of his hearers even when dealing with statistics. I never heard of his putting his charm to the test of a monologue on the details of proper hospital construction and management.

Again conditions are so different in each institution that it must work out its own salvation, but I could not see my way clear to closing this paper without briefly referring to a few of the general principles applicable to all conditions and perhaps touching upon a few specific factors in the breaking of that peace which should be characteristic of the buildings in our charge.

First the site for a new hospital should be selected more with reference to its surroundings than to its convenience of access for visiting doctors and friends. It is needless to say that it should be removed as far as possible from the roar of city traffic or factory machinery. Where the site is already chosen the Governing Board should be ever alert to prevent the coming of undesirable neighbors and to seize every opportunity for the removal of such as are already too near.

Secondly, much of the quiet of an institution depends upon its construction. Hospital architecture has become a science and art by itself, and in a new building or even remodelling or changing an old one the most expert direction should be secured. Floors can now be laid so as to be nonconductive of sound, doors hung with noiseless automatic checks and springs, windows to glide smoothly on large ball bearing pulleys, walls to confine sound to their own enclosures. These attainments are beyond the or-

*Read at the annual meeting of the Canadian Hospital Association, held in the Royal Victoria Hospital, Montreal, on March 25, 1910.

dinary house contractor and should not be expected from him.

Thirdly, in arrangement of departments much may be accomplished even in an old hospital by readjustment. The Medical and Surgical wards should be separated from each other. A recovery room will be necessary off each surgical ward in order that convalescents and others may not be subjected to the depressing influence of the operative recovering from chloroform. For obvious reasons the obstetrical and children's wards should be in a separate building. The Lying-in room should be situated in a part of the building where its sounds cannot reach the ear of other patients. Ward pantries should be far enough away from the rooms that the sound of washing dishes will be inaudible. Again if there is one thing more than another which patients complain of it is the constant ringing of bells. Replace them with the electric light signal system.

Fourthly (and you will be relieved to hear me say lastly), is the most important factor of all—the personnel of the staff. Let us begin with the Superintendent. This official should teach by precept and example that quietness is the one thing needful in the best interests of all concerned. Frequent visits to the words of the institution will have a good effect in preventing any disturbance. Disorderly conduct on the part of any individual in the hospital must not be tolerated.

Next I consider the interne. A conscientious, faithful one is one of the most valuable assets a hospital can have. His influence for calmness and quietude will be far reaching, while that of one is foolish and frivolous will work for disorder and mischief. A great difficulty met with is the self-importance and over-confidence of the recent graduate interne. He illustrates the word of Goldsmith "For e'en though vanquished he could argue still, while words of learned length and thundering sound amazed the gazing rustics ranged around, and still they gazed and still the wonder grew that one small head could carry all he knew."

One hears him going down the wards walking on his heels as though he had gained considerably in weight since the night he received his degree amid the glare of lights and the singing of his praises for the great work he has just completed. Sad to relate many a man never recovers from this head swell until after he has left the hospital. This type of man and the jocular one is never satisfied until he has proved his wit by throwing some nurse into a convulsion of laughter alike do violence to the quiet decorum of our wards. It is most important, therefore, that great care be taken in selecting men to fill that position.

Of all the individuals connected with a hospital there are none who can do more to disturb its peace or blast its prospects than the nurses, therefore it is of utmost importance that only capable, conscientious women be chosen to fill the ranks of the nursing profession. Lady Superintendents should weed out all those who show a lack of sound, sensible, dependable qualities during their probationary days. Even after nurses pass the probationary period if they persist in disturbing the wards by engaging in foolish talking and laughing with house surgeons or visitors they should be severely reprimanded. One who habitually disturbs her patients in this way does not care for their welfare, hence she will neglect them and doubtless make false records. She is not conscientious and faithful, hence the sooner the hospital is rid of her the better for all concerned. We all know a great deal may be accomplished by keeping nurses in check by having a faithful head nurse in charge of the wards. Not only will she have a good effect in this connection, but every one on the ward will do his or her work in a quieter manner.

By no means is all the unnecessary disturbance made by those who are intra murals at the institution, for many of the disagreeable sounds are made by some members of the visiting staff. Who has not heard two of the jovial sort in the corridors have a good laugh over something, forgetting that they are harassing some poor patient in the adjoining room. Then again, shall I venture to say it, have you not heard the wide vocabulary of profanity which some of the physicians and surgeons have, especially when something goes wrong on the ward? However, in the majority of instances the doctor is a great help in keeping things quiet by wielding an influence over his convalescents, preventing them from becoming too hilarious.

We shall next turn our attention to the visitors. Many of these are so inconsiderate that they create considerable disturbance in walking heavily along the corridors or by loud talking and laughing. It seems to me the only way to deal with this is to limit the hours for visiting, and secondly, to request them to keep as quiet as possible.

We are all cognizant of our inability to reach perfection and have absolute silence, yet it is not unreasonable to think that each and every one may move closer and closer to that ideal. I am convinced that by eternal vigilance we shall be able to change the atmosphere of our hospitals from that of ceaseless and bustling activity into one of calmness and repose, wherein even the most fastidious neurasthenic will be unable to find a source of irritation and one in which every weary sufferer may find rest, sweet rest.

THE CATCHING COLD PHOBIA.

By WM. BRADY, M.D.,

ELMIRA, N. Y.

Insofar as ordinary minds, subject to mortal error, can grasp the truth in the teachings of Christian Science, we have, in Mary Baker G. Eddy's explanation of disease, an admirable definition of hysteria—the disease from which Christian Science chiefly derives sustenance—viewing hysteria in the light of psychic analysis. It may well have been "catching cold" that Mrs. Eddy had in mind when she wrote that "disease arises from association calling up the fear that creates the image of disease and its consequent manifestation in the body." Certainly it is nothing else than the fear of "catching cold" that has created the image which manifests itself so impressively in the difficulty experienced in persuading the tuberculous to live outdoor lives and in the application of the outdoor treatment of pneumonia, in private practice, during cold weather. Indeed, the catching cold bogy proves a most deplorable obstacle to present methods of palliating and eradicating disease, and the responsibility for the well-nigh universal worship of this false image rests largely on our own shoulders since the stupid habit of speaking of "taking cold" prevails quite as widely among physicians as the laity.

One can scarcely form an adequate conception of the abuse of this nonentity unless one makes an en-

deavor to avoid reference to cold, in the colloquial sense, in conversation with patients. In general practice it is really a problem to elicit a history from a patient of even high intelligence without recourse to this vicious phrase; fully nine-tenths of our patients believe, if they have not already been told, that their ailments are caused or aggravated by "taking cold." The very exceptional case in which the history does not gratuitously open with a "cold" somewhere or other will promptly rise to the bait of a leading question, put by the physician, bearing on the probable cause of the illness. Therefore, the adjective universal is advisedly applied to this abuse in the preceding paragraph.

Conscious of this unfortunate state of affairs, we should consider it our duty to show our patients, at every opportunity, the utter absurdity of their delusion. This, of course, will prove a gigantic task so long as medical men persist in the use of the catching cold sophistry as a cloak for diagnostic ignorance—for such it is, in all truth, at all times. Many practitioners greedily seize on this accommodating phrase as a useful scheme for hedging on the diagnosis pending the period required for the signs to disclose the true nature of the illness. These magicians are always capable of turning a "slight cold" into measles, influenza, typhoid fever, tuberculosis, or whatever the exigency may demand. A very few of the craft, fortunately, become so expert at this trick of the trade as to conceal the mark of unclean instruments or unwashed hands, in certain cases of septicemia, under the familiar label "she has taken cold"—a crime to which we, as a profession, are accessory when we do not try to discourage the widespread catching cold fallacy that permits it.

A bulletin from the bedside of a certain "exposed" politician recently stated that "the senator has contracted a very heavy cold, which it is feared may settle on the lungs!" We are almost daily consulted for "colds" which, by virtue of their specific gravity, "settle" even lower—in the epididymis or in the female pelvis, for example. Finally, there is that joy of the blunderbuss therapist, the diffuse or general cold which "settles all over" and is consequently to be attacked by figuratively closing the eyes and shooting at random a scattering charge of some such junk as "cold-improved" or "cold-preferred tablets" into the victim's body. It is surprising how many survive such an attack, only to pass the remainder of their lives at the popular pastime of dodging draughts.

Our medical ancestors, if we may except their intimate comprehension of the ubiquitous itch mite, were quite innocent of any practical knowledge of bacterial infection. They were very willing victims of the catching cold delusion because it served them excellently as a useful factor with which to account for an appalling amount of otherwise mysterious illness. In ye olden times the doctors did not auscult the chest, but rather they searched for a hole in the patient's jerkin. Through that hole they managed to trace bronchitis, tuberculosis, pneumonia, even rheumatism (*rheuma*, catarrh, a flow) and a host of other maladies. So it was only natural that, in their benighted wisdom, they should have fostered the catching cold idea so fondly, to hand it down to us—a veritable lemon among the fruits of the forefathers' pristine medical lore.

But however useful it may have been in the past, have we to-day any further need for it? Does it not cost too dear a price as a hindrance to medical progress? Medical authors no longer claim that cold causes disease other than frost-bite, but most writers assert that "cold merely predisposes to infection by lowering resistance"—which plausible words are but the expression of a reluctant compromise with the scientific proof educed by the bacteriologists to shatter the hereditary traditions relied on by the champions of the catching cold idea. How much influence cold may have on the body resistance is admittedly an open question; experimental evidence is available, however, to show that repeated applications of cold insufficient to produce frost-bite as, for example, plunges and shower-baths, tend to raise the opsonic index. Moreover, the "tonic effect" of porch bedrooms, open-air exercise, and getting out in the weather is to-day generally recognized. When authors speak of "cold and exposure" in this connection, they presumably mean the environment of the average individual whose occupation requires him to go forth into rain, shine, hail, or snow regardless of temperature and humidity—if not, then what else? But here it is hopeful to note that Osler, in giving the etiology of acute coryza, makes no mention of cold or of "catching cold," rather directing attention to the *Micrococcus catarrhalis* and the epidemic character of the disease.

Now, if the proverbial "cold in the head" be thus denied its mooted dependance on cold, the venerable catching cold chimera bids fair to vanish utterly from the textbooks of another generation. Therein will be substituted, instead of the hackneyed repetition of "lowered resistance from cold and exposure," an elucidation of the influence on the opsonic index of dietetic errors, unhygienic clothing, and the excessive heat and defective ventilation of civilized buildings.

Accepting Webster's definition of the word draught there can be no ventilation without draughts. It is absurd and futile to instruct a family to "secure good ventilation, but avoid draughts." More correctly, we should say: "Be sure to have a good draught." A draught becomes harmful only when it carries dust and bacteria to the patient's nostrils. A current of clear, moist, cold air cannot injure the body, though it may at times be uncomfortable. There is no denying that a stream of cold air playing on a fractional portion of the freely perspiring body after violent exercise may be followed by local soreness and stiffness. This ill-named "muscular rheumatism," however, is only an indication of dietetic excess or sedentary habit, since it does not occur when metabolism is normal.

Writing on the fresh-air treatment of surgical tuberculosis in children, Whitbeck says: "The wards have been so arranged that a free circulation of air can take place. . . . The windows are never closed day or night, summer or winter. The word draught is not known in the vocabulary of Sea Breeze Hospital." How refreshing is such untrammeled progressiveness in contrast to the egregious custom of cautioning patients against "exposure!" Carrying Whitbeck's suggestion further, could we not advantageously drop the word draught from our general medical vocabulary? The schematic diagram here shown illustrates one faulty method in vogue for dodging draughts. The board placed beneath the lower sash of an open window cannot modify the physical law by which cold air falls and hot air rises; the best it can do is to alter slightly the direction in which the confined current of much dreaded air approaches the body surface.

What is here said regarding draughts will, it is anticipated, be repudiated by the majority of our senior colleagues. Still, when we remember how innumerable are the plans exploited in works on hygiene and sanitation for securing fresh air in homeopathic doses, and when we also remember that somewhere in the neighborhood of the thirty-fifth year of life one's mind, according to Professor James, becomes "set" like plaster-of-Paris and one's opinions correspondingly fixed, we expect this view to meet with hostility in some quarters.

A much quoted argument of the catching cold exponents is that respiratory diseases prevail mostly during the changeable weather of spring and fall and are less common in midsummer. This incontrovertible fact calls attention to the misguided methods commonly in use for heating our offices, dwellings, stores, factories, schoolrooms, and railway cars.

With steam heat, fuel economy and free ventilation are at cross purposes, the less ventilation permitted, the greater the heating capacity of a given plant and therefore the less fuel required. Stoves with draft-pipes are somewhat better, since by heating the atmosphere unequably a certain

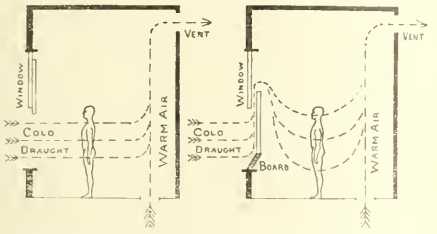

Diagram showing the futility of dodging draughts; on the left is a wide-open window with "direct draught"; on the right is a window fitted with a board "to prevent draught."

amount of ventilation is enforced. But hygienic requirements are best fulfilled by the hot-air furnace, provided the air is properly moistened and the intake is from a clean source; a hot-air furnace heats satisfactorily only when ventilation is good.

With all forms of heating, but particularly with steam heat, the American habit, extravagant as in all else, demands for comfort a temperature of 75° F., and in many instances the thermometer is kept hovering around 80° F. In England, on the contrary, 65° F. is considered a comfortable average, and this assuredly approaches the hygienic standard. American schoolrooms, often abominably ill-ventilated and overheated, furnish the foul air and enervating warmth that unquestionably act as factors of the respiratory and eruptive diseases to which school children are so much exposed. However, it is hopeful to know that in Buffalo, Rochester, Chicago, and elsewhere open-air, unheated schoolrooms are becoming very popular.

The unfailing benefit derived from the administration of an active saline cathartic in acute coryza, for instance, gives a hint of the connection between dietetic errors and respiratory diseases. This intimate relationship is at least partly explained by the direct communication that exists between the portal system and the venous plexuses of the esophagus, pharynx, and nose. Overeating equals or, perhaps, outstrips alcohol as a predisposing factor of respiratory infections, and to eradicate such factor an ounce of Fletcherism excels a pound of pepsin or a barrel of salts.

A third important predisposing cause of respiratory disease is improper underclothing. Since discarding his hairy coat, man has ever felt the need of a substitute in this climate, and there is no adequate substitute for hair but wool. Encased in a light, porous, knitted suit of woolen underwear with woolen stockings, the body enjoys much the same protection against sudden temperature changes originally afforded by hair. Thus arrayed, comfort alone need be consulted as to the amount and weight of the outer garments or wraps. Wool, being a slow heat conductor, permits the body surface to cool gradually on passing from a warmer to a colder atmosphere, so that the vasomotor system adapts itself naturally and there is no congestion produced. Cotton, on the other hand, is an excellent heat conductor; it dissipates heat so rapidly, under similar conditions, that the vasomotor function of the ordinary individual seems unable to cope with the gymnastic strain demanded, and therefore a large volume of blood is driven toward the great splanchnic or thoracic areas, constituting an active congestion of one or another organ, which condition invites infection as an immediate effect, or induces hyperplasia of tissue as a chronic sequence.

"Chest protectors," throat mufflers, abdominal binders, and pneumonia jackets are contrivances based on such untenable theories as hardly to deserve condemnation, yet physicians often prescribe them. They are surviving relics of that interesting period of the dark ages when spells, humors, and witchcraft held sway, and cold was believed to penetrate directly through the skin that was not amply protected against draughts and the dread night air. Coddled throats and chests are noticeable with undue frequency among our cases of respiratory disease, and in this instance, *post hoc ergo propter hoc* seems a safe deduction, when we are mindful of the lowered mortality recently obtained in the treatment of pneumonia and tuberculosis by cold air.

Laying aside unfounded traditions and depending solely on our present knowledge, it may be confidently affirmed that the vulgarly listed causes of respiratory disease, such as cold, dampness, exposure, wet feet, and draughts, are, for all practical purposes, entirely negligible factors, and the only precaution necessary against them is the effort to secure bodily comfort, which is purely instinctive, though very commonly misguided.

In conclusion, our contentions are:

(1) Cold has no demonstrable etiological relation with respiratory disease.

(2) Clean draughts are not only harmless, but salutary, being requisite for perfect ventilation.

(3) The phrase "catching cold" is meaningless, misleading, undignified, and obsolete.

(4) The groundless fear of cold, fostered by the abuse of this misleading phrase, constitutes a form of hysteria that opposes and embarrasses earnest therapeutic measures.

(5) So far as we now know, the true predisposing factors of the various respiratory diseases (acute and chronic) are dietetic sins, unhygienic clothing, overheated apartments, and defective ventilation.

(6) Prophylaxis therefore consists in directing intelligently man's instinctive effort to secure bodily comfort, together with reasonable isolation of every case of respiratory disease.

1008 Lake Street.

SOME REMARKS ON THE TREATMENT OF PELLAGRA.

By GEO. M. NILES, M. D.,

ATLANTA, GA.,

PROFESSOR OF PHYSIOLOGY, SOUTHERN COLLEGE OF PHARMACY; ASSOCIATE PROFESSOR OF PHYSIOLOGY, ATLANTA SCHOOL OF MEDICINE; GASTROENTEROLOGIST TO THE TABERNACLE INFIRMARY.

Just now in several sections of this country pellagra is appearing with alarming frequency—a frequency not accounted for by more prompt recognition of incipient and atypical cases, as some would have us believe. In this brief paper the theories as to its origin and the diagnostic features will not be discussed, as leading too far afield.

While admitting that many of the therapeutic measures invoked to combat this disease have not been productive of success, the writer feels that, in the light of his own experience, as well as data furnished by several careful clinicians, we have much reason for encouragement, and little excuse for the attitude of wooden pessimism assumed by some present-day observers.

Pellagra is with us. As the late Grover Cleveland said: "A condition and not a theory confronts us," so, while the zeists and antizeists are waging their learned warfare, it behooves us to be up and doing with the actual cases on hand.

The treatment naturally dividing itself into dietetic and medicinal, we shall first consider the dietetic.

Until it is disproved that spoiled maize or its products are factors in the causation of this disease, it is wise to give the patient the benefit of the doubt, and prohibit all food and drink (alcoholic or otherwise) derived from this source. A point overlooked by some is the fact that many of the cheaper grades of flour are adulterated with "corn hearts," so that the pellagrin may be unknowingly ingesting a large proportion of maize every day. The only way to avoid this is to use the best quality of flour from a known and reliable source, if possible.

Other dietetic regulations depend altogether on the state of the gastrointestinal tract, or as to the presence of constipation or diarrhea, and need not vary materially from the regimen instituted for the same manifestations of digestive disquietude set up by other diseases. Speaking generally, a liberal diet is indicated, the flesh proteins being specially well borne. The writer also ventures the opinion—which opinion is not as yet widely accepted—that the diarrhea appearing early in the course of pellagra is of central origin, and, to an extent, compensatory. It would naturally follow, therefore, that a diarrhea of this sort need not entail a too limited dietary. Later on, when the diarrhea has become inflammatory the physician may to advantage eliminate articles of food containing much cellulose, or yielding after digestion a residue of irritating particles. In any event, so far as is consistent with local conditions, the patient should be nourished to the limit of assimilation.

Coming to the medicinal treatment we enter into a maze of contradictory opinions, where set methods of management yield such divergent results that the conscientious seeker after light becomes almost bewildered. It is evident that in many respects we are still floundering among the shallows and breakers, not having as yet been able to land on the solid ground of therapeutic certainty. Realizing these facts, the writer, from interviews and correspondence with some well-known practitioners, as well as from a fairly broad personal experience, is endeavoring to give a résumé of the best recognized methods now in use.

Dr. R. T. Dorsey, of Atlanta, gives one of the most optimistic reports. After treating about thirty cases with atoxyl, etc., with unsatisfactory results, he began giving a combination of Fowler's solution and a saturated solution of potassium iodide (two parts of the former to one of the latter) in ascending doses up to the physiological limit. The diarrhea he controls with bismuth subgallate and powdered opium. Constipation, when present, is best relieved by castor oil, and this should be carefully watched for. Dr. Dorsey contends for an absolute milk diet with an abundance of lime water while there is acute buccal and intestinal irritation, followed by a liberal diet when admissible. He reports nine consecutive recoveries, several of whom have passed a spring without a recurrence.

Dr. E. J. Wood, of Wilmington, advises large doses of atoxyl (0.25 to 0.50 gram) hypodermically, giving the dose every third or fourth day, and arsenite of iron on the other days. In the first two years of the disease he considers this treatment highly efficacious, but does not hold out much hope after the third year, nor in fulminating cases.

Lombroso's teaching on therapy has had such a profound effect that it seems well to give some of his views. He looks on arsenic as in a certain sense an antidote for the toxins of spoiled maize, to which he attributes pellagra. As an antidote he compares it to the action of opium in alcoholism and mercury and the iodides in syphilis. He uses arsenic in the form of Fowler's solution in doses of 5, 10, 15, 20, and 30 drops, or in the form of pure arsenious acid, dissolved in slightly alcoholized water, in doses of one-fortieth to one-twentieth milligram, increasing up to tolerance. The administration of arsenic is suspended for a few days from time to time.

Among the dangers incident to the exhibition of this drug are the appearance around the neck of an herpetic eruption, profuse salivation, anorexia, vomiting, diarrhea, palpitation of the heart, syncope, burning in the pharynx and stomach, great muscular weakness, and bronchitis.

Some types benefited by arsenic are cases with marked marasmus, cases with incipient paresis, cases with sitiphobia (gastralgic type), cases with vague mania, but not marked delirium, cases in the aged but not decrepit.

The types generally not benefited compose the very young, well-nourished and robust cases, those with systematized delirium, those with mental aberration of several years' duration, cases having lobar pneumonia, tuberculosis, albuminuria or severe vertigo.

For grave vertigo Lombroso recommends the tincture of cocculus orientalis in doses of 3 to 5 drops daily, progressing slowly to 30 drops a day. Incidentally, it might be mentioned that the writer has used the cocculus in two cases where vertigo was a troublesome symptom. It was carried up to 12 drops daily in one case, and 15 drops in the other, with evident benefit.

It has been unfortunately the experience of many that the Fowler's solution would not be tolerated where the gastrointestinal irritation was to any extent acute, so that preparations containing arsenic or arsenic and iron suitable for hypodermic use have necessarily been indicated. A crying need

just now is for a non-toxic arsenic preparation less dangerous than atoxyl, and there is strong probability that it will soon be secured.

The simple erythematous rashes on up to sloughing conditions of the hands or feet may be alleviated or cured by the bland ointments, such as oxide of zinc ointment or a 2 per cent. ointment of boric acid. Avoidance of the sun's direct rays, or even very bright light, is advisable during the continuance of the erythema. For the intense burning of the hands and feet, so often complained of, compresses saturated with a mild solution of bichloride of mercury, ice cold, and applied at frequent intervals, will often afford marked relief.

For the sore mouth, a solution of thymol, one grain to the ounce of water, a little alcohol being used for a solvent, will generally prove sufficient. Also a 25 per cent. solution of boroglycerin is helpful. For the aphthous spots in the mouth or on the tongue, touching with silver nitrate (ten grains to the ounce of water) every other day is in most instances efficacious.

For the occasional constipation either castor oil or enemas will serve, drastic cathartics being out of the question.

For the much more frequent diarrhea the writer has obtained satisfaction from bismuth betanaphtol and resorcin given with the official mixture of rhubarb and soda as a vehicle. This failing, powdered opium, tannigen, or heavy doses of bismuth subgallate are indicated.

When there is a paucity or absence of free hydrochloric acid in the stomach contents, a lavage every alternate day with a 1-1000 solution of boracic acid, sodium salicylate, thymol, creolin, or ichthyol may be employed to advantage. When those medicated douches are used, however, it is well to start with a mild saline solution, then the medicated fluid, then conclude with plain water.

Special treatment of the mental symptoms, appearing as they do in such Protean shapes, will not be discussed in this paper, as it would lead into a branch of therapeutics in which the writer would defer to the alienists.

As a *dernier ressort*, several clinicians have used direct transfusion, either from a supposedly cured pellagrin, or from a healthy person. Though this method has met with varying results in different hands, and is fraught with many difficulties and dangers, we realize that desperate conditions require desperate remedies, and feel that under certain circumstances transfusion is entirely justifiable.

I take the liberty of quoting *verbatim* a portion of a personal communication from Dr. H. P. Cole of Mobile which fairly illustrates the present status of this procedure: "To date we have transfused 17 cases, these having been transfused for periods now of from two years to one month. Seven deaths and eleven recoveries. Only one case has had a recurrence. We have noted no greater benefits from donors who have had pellagra than from donors who never had the disease, though of course the cases are too few to make valuable statistics. No cases have been transfused except as a last resort, so, considering the types of cases, we feel that transfusion offers more by far than does any other procedure in the terminal stage. Many cases never come to necessity for transfusion, and we have had a number whom we refused transfusion, and who recovered under institutional and constitutional treatment. We have had two cases die on the way to us. That will give you an idea of the type we have to work on. It is difficult to tell just when to transfuse. Now we attempt the usual remedial agents persistently, and failing in this, we resort to transfusion. Cases who have lost their muscular reflexes are hopeless for any measure. Of the seven deaths, two might well be excluded, as there was no appreciable amount of blood transfused, the operation being attempted in very unsuitable surroundings. These two, however, are included. No ill effects have been noted from the operation, careful selection of donors as to hemolysis being essential, and care at operation to prevent acute dilatation of right heart. The most suggestive finding is this: All cases that get well show improvement within a day or so, and go right on to recovery. The fatal cases did not at any time after operation show any improvement. All recovered cases gained from five to eight pounds the first week."

In conclusion I wish to sound an optimistic note regarding the therapeutic outlook for pellagra. Within the last four months I have lost one case, and dismissed as apparently cured five. Five others are under treatment, seemingly doing well.

Many studious minds are focussed upon this disease just now, and we may confidently hope to find ere long a solution to the heretofore vexed question —how to treat pellagra.

409-410 Candler Building.

Antitoxic Action of the Bile.—Gustavo Padoa has made personal experiments with reference to the antitoxic qualities of the bile, making use of fresh feces from a patient sick with catarrhal enteritis for the tests, to which was added fresh ox bile or human bile obtained from a patient who had recovered with a biliary fistula. After reporting the experiments in detail he gives his conclusions. Ox bile in the proportion of 1-5 has an active antitoxic effect against the bacillus coli contained in feces. Human bile has the same effect, but to a much less marked degree. This power is lost when the preparation has been placed in the thermostat for 18 to 23 days. It is also nil when added to old cultures of bacteria. Even when the antitoxic effect of bile is marked there is no effect on the development of the bacteria, which are no less in number than before the test was made.—*Rivista Critica di Clinica Medica.*

Primary Febrile Herpes.—G. Bruno discusses the probability of the occurrence of herpes accompanied by fever as a primary disease, apart from the presence of another infection. He concludes that there is a true primary, febrile herpes, and that it is not very rare, but is often confounded with herpes zoster and symptomatic herpes. He gives the history of such a case observed by himself in the person of a man of twenty-four years of age, who was attacked suddenly with chills, fever, and delirium, and after two days developed a cutaneous eruption of herpes vesicles, arranged in groups along the course of the trigeminus. He had ocular disturbances also. If this disease is not the result of some specific microorganism it is probably due to an intoxication and endogenous origin; perhaps to toxins generated by the habitual inhabitants of the intestine, which for the time have become more virulent than usual. The diagnosis is easy after the eruption appears.—*Annali di Medicina Navale e Coloniale.*

Clinical Anaphylaxis.—E. Lesné defines anaphylaxis as the sensitization of an animal to an organic substance by injections of the substance. Later injections will then cause a reaction of the nature of fever, gastrointestinal symptoms, urticaria, etc. Anaphylaxis may be obtained to bacterial toxins, and to any material that is an albumose, or that resembles them in composition. Egg albumin, milk, oysters, clams, mushrooms, and other vegetable substances cause poisonous symptoms as a result of anaphylaxis. Some persons are not at all subject to anaphylaxis, while others are. The author thinks that in susceptible persons there is a profound alteration of the mucosa of the stomach. The symptoms are sudden intoxication, abdominal pains, vomiting, constipation, or diarrhœa, lowered arterial tension with collapse, and skin symptoms. Cyclic vomiting in children is of this nature.—*Annales de Médecine et Chirurgie Infantiles.*

MEDICAL RECORD.

JUVENILE COURTS AND THE STUDY OF THE JUVENILE DELINQUENT.

ONE of the salutary results of the establishment of children's courts in metropolises should be a more intelligent study of the juvenile delinquent. The normal delinquent youth differs necessarily from the offender of defective makeup or degenerate stock. The boy criminal differs radically from the girl offender. Youthful offenders differ from adults of the same class. The children also differ, as to the relative frequency of certain offenses, according as they dwell in agricultural, manufacturing, or commercial communities.

Much interesting information along these lines is brought out by State Attorney Rupprecht, a practitioner in the children's court at Munich (*Münchener medizinische Wochenschrift*, July 26). In that city the children's court takes cognizance of all offenders between the ages of 13 and 18, inclusive. The lad or girl of healthy stock must at this period be regarded as potentially a criminal, because character and will are undeveloped, and experience—that best of teachers—has not yet had its innings. Desires are strong, overpowering; and inhibition is weak. Hence many offenders, absolutely free from taint, are merely the product of their environment. Such must not be confounded with defectives. Munich, as a city of superior educational facilities for the masses, and without certain drawbacks native to mill towns, has but a small contingent of youthful criminals. In a population of nearly 600,000 there are less than 500 serious offenses a year committed by juveniles. Naturally petty offenses—such as begging—multiply this total fivefold, but with these we are not concerned.

Theft is the great offense of youth. It overshadows all others so far that the latter appear almost freakish. Thus, but two boys were arrested in a given year for torturing animals; while the convictions for violence against the person, rape, pederasty, and subsisting on prostitutes were hardly more numerous. There were but few arrests for drunkenness. When we consider that the offenders in such cases are likely to be either defectives or boys near the superior age limit, these may almost be eliminated from the ranks of juvenile offenders proper. To return to offenses against property—in this case confined chiefly to theft: It appears that the boy steals in an unpremeditated fashion, while the girl has a plan. Boys tend to steal "junk"—not, it appears, to sell, but as raw material for making playthings. Girls tend to appropriate cosmetic articles.

We have heard much in the United States as to the dangers of moving picture shows in tempting boys to pattern after burglars and highwaymen. This theoretical position may be quite offset by the actual knowledge that in Munich boys steal in order to be able to visit these entertainments (which, for all we know, may be highly moral). The temptation to visit these attractions is so strong that even a "good" boy may not only forego his dinner, but pilfer the price of the entertainment. He will do as much to get hold of a Nick Carter or Sherlock Holmes story. The boys in Munich also steal in connection with deep-laid plans for visiting the frontier and fighting savages. But the Bavarian youth must be much more long-headed than the Anglo-Saxon in this respect, for he usually steals a horse and firearms before sallying forth. Of course, he robs the family strong box for the sinews of war.

In regard to shoplifting and pilfering by girls it is moving to note that they sometimes steal in order to make a present to a favorite school teacher. One took the flowers off a grave for this purpose.

When caught in the act of a theft, a boy usually confesses, repents, and refuses to betray his associates. A girl, Rupprecht says, lies until the last minute, and then endeavors to throw the blame on some one else. But boys almost always rob in bands, while girls usually act alone. A boy seldom robs his employer, but some outsider; the reverse is the case with girls, who, since they pilfer cosmetics, adornments, etc., must almost necessarily rob their mistresses. Of much less interest are the crimes of degenerates and defectives, who form a class by themselves. The chief value of Rupprecht's study is that it deals in the main with normal subjects, the policies advisable in dealing with whom have hitherto received comparatively little attention.

CULTIVATION OF THE LEPER BACILLUS BY CLEGG'S METHOD.

DURING a period of some years excellent experimental and research work in connection with leprosy has been in progress at the U. S. Biological Laboratory at Manila and at the Leprosy Investigation Station, U. S. Public Health and Marine Hospital Service, at Kalawao, Molokai, Hawaii. The material for such studies is ample in the Philippine Islands and in Hawaii, and naturally full advantage has been taken of the opportunities afforded. Clegg made a preliminary report upon the cultivation of the *Bacillus lepræ* at the sixth annual meeting of the Philippine Islands Medical Association, which was held at Manila on February 11, 1909, and reported in the Philippine *Journal of Science*, and in the same journal for December, 1909, he gives further results. In the first report it was stated that he had succeeded in cultivating, from the spleen and skin nodules of typical cases of leprosy, an acid-fast bacillus which grew upon agar in symbiosis with amebas. The amebas had been obtained from a

dysenteric stool and were cultivated with the cholera vibrio. "At the time of the first publication," states Clegg in his second report, "the acid-fast organism had been obtained in symbiosis with amœbæ from the spleen in two cases and from skin nodules in three other cases of leprosy, but had not been isolated in pure culture. Since then similar cultures have been obtained from leprous tissue in three additional cases, and from two of these the acid-fast organism has finally been isolated in pure culture."

Clegg has throughout his investigations used the greatest care to avoid experimental errors and is satisfied that the results of his work are to be relied on.

It is worthy of notice that the majority of lepers from whom the material for the cultures made by Clegg was obtained had tuberculous lesions in their lungs, but the tissues used for the cultures showed no evidence of tuberculosis. The animal inoculations described by Clegg prove that the acid-fast organism cultivated by him is not the tubercle bacillus. The following is a summary of his results: 1. The leprosy bacillus was first cultivated from leprosy material in symbiosis with other unidentified bacteria and amebas and later from other cases in symbiosis with amebas and the cholera vibrio. 2. By heating a symbiotic culture of amebas, cholera, and leprosy for half an hour at 60° C. and incubating the leprosy bacillus was obtained in pure culture. 3. The leprosy bacillus isolated in this manner grows readily on the ordinary laboratory culture media. 4. The bacillus is pathogenic for guinea pigs, subcutaneous inoculations having caused lesions which macroscopically and microscopically resemble the leprous lesions of human subjects.

The statement by Clegg that the leprosy bacillus could be cultivated artificially did not receive the attention that its importance deserved. In the first instance the difficulties in the way of solving the problem are so great that students were discouraged from making similar investigations. However, Donald H. Currie, Walter R. Brinckerhoff, and H. T. Hollmann, of the U. S. Public Health and Marine Hospital Service at Kalawao, Molokai, Hawaii, for some months have been conducting experiments of a like nature and have just announced in Public Health Reports, August 26, 1910, that their efforts have been crowned with success and that they have confirmed the work of Clegg in cultivating the *Bacillus leprœ* on artificial media. This is to say that they have been so far successful that an acid-fast bacillus has been grown on artificial media four times from three cases of leprosy, and one of these obtained in pure culture.

In summarizing their work these investigators state that they have each succeeded independently in establishing ameba-cholera-lepra cultures from cases of leprosy. Dr. Currie has obtained a stain in pure culture. The ameba-cholera-lepra cultures have been carried through from three to ten generations. The pure culture is now growing in its third generation.

This appears definite enough, and although perhaps further experiments will be required to prove the point absolutely, the conclusion may be come to that an acid-fast bacillus resembling the lepra bacillus as seen in human tissue can be isolated and grown in pure culture by the method of Clegg from the active skin lesions in cases of leprosy. The importance of this finding is obviously very great from the practical as well as the scientific points of view. If Clegg's conclusions are finally confirmed a very long step in advance will have been made in the study of leprosy and doubtless a new era opened in its treatment. It is gratifying to know that this progress is due to American scientific men.

TESTS FOR RENAL ADEQUACY.

The numerous tests introduced in recent years in respect to renal permeability and sufficiency have been employed almost exclusively in the case of surgical kidneys; in other words they are essentially differential in character. Since "medical" nephritis is said to be always bilateral, such differential tests cannot have any field of usefulness for internists. Few of the numerous tests thus intended to indicate the relative integrity of the two kidneys have shown any intimation of pathognomonic value. If they agree among themselves as to positive or negative findings such a coincidence is worth heeding, perhaps; but individual tests may not only be unsatisfactory in themselves; often they flatly contradict one another. It becomes evident, therefore, that the greater our number of trustworthy tests the greater the chance of a consensus in findings; and with a sufficient degree of consensus the element of chance or accident will be eliminated.

Wohlgemuth (*Berliner klinische Wochenschrift*, August 1) finds that three of the older tests possess value. These are cryoscopy, the phloridzin test, and the indigocarmin test, the first named being the most sensitive. To these he would add a diastase test, based on the fact that normal renal tissue excretes a diastatic enzyme, which fails to appear in the urine in direct proportion as the kidney parenchyma is compromised. The technique is based naturally on what we know of the detection of diastase in fluids in general. The urine is treated with solution of soluble starch 1-1000; and after exposure in the incubator for a variable interval to allow a digestive reaction the fluid is tested with an iodine solution in order to determine the degree of starch digestion.

The author has hardly gone far enough in his experiments to enable him to publish a full-fledged technique such as might be incorporated in a textbook. But whereas he required at the outset twenty-four hours for a test, he has recently been enabled to announce differential results in renal activity as early as the first half hour. This fact very likely influenced him to place his method on record. At the same time the test, requiring as it does a fractioning process, ought to be further simplified before introduction.

Surgical Treatment of Exophthalmic Goiter.

Perhaps as little is known of a beneficial treatment of exophthalmic goiter as of any disease. The surgeons claim that in operative measures lies the

only hope of permanent relief, while physicians do not appear to be able to point to any course of treatment which will insure successful and permanent results. A certain amount of scepticism may exist in regard to the favorable outcome of surgical procedure in Graves' disease, but surgeons can undoubtedly direct attention to the satisfactory issue of numerous operations. Zapffe in *Surgery, Gynecology and Obstetrics* states that the mortality from operations for exophthalmic goiter is exceedingly small and must be ascribed in most instances to ill-advised operations. When goiter develops with great rapidity early operation is contraindicated, as it is also in those cases in which there exists a cardiac lesion, with severe nervous disturbances, especially delirium, and when there are present degenerated heart muscle, irregular pulse, or low blood pressure. In Kocher's clinic 254 patients have been operated upon for exophthalmic goiter; of these 83 per cent. were cured, all were benefited, and but nine died. Krecke has collected figures referring to 888 operations in five clinics, the mortality rate being 9 per cent. He, however, has not seen the exophthalmos subside entirely in any case. Charles Mayo in the last two hundred operations has had a mortality of 5 per cent. Of 167 patients traced, 70 per cent. were improved, cured, or greatly improved, and 94 per cent. were cured, improved, or somewhat improved. Formerly, before the physiological importance of the parathyroids was fully appreciated, tetany followed in many cases of thyroidectomy, but it now occurs but rarely. Where the disease has so far advanced as to render necessary the complete removal of the gland Kocher has transplanted parathyroids with fairly good results.

Lumbar Puncture in Mental Diseases.

Lumbar puncture gives valuable information in many diseases of the brain and spinal cord, and its results in diseased conditions, and the information of diagnostic and prognostic value obtained thereby make this treatment worthy of further investigation. J. Roubinovitch and H. Qaillard, in an article on this subject published in the *Gazette des Hôpitaux* for June 28, 1910, give the results of some investigations made by them into the conditions of pressure found to exist in the spinal cords of patients suffering from mental disease of various kinds, but especially general paresis. Their investigations included tests made in over sixty individuals. They did not find the severe high tension of meningitis, but an increased tension relative to the normal. In general paresis the tension differs according as the test is made in a period of excitement or one of repose, or in the final state of marasmus. In periods of calm the tension is 10 to 15 centimeters; with a period of excitement elevation of tension begins, and when a condition of ictus epilepticus appears it rises to 19 to 23 centimeters. The authors were struck with the frequency of lowered arterial tension after lumbar puncture. In rare cases it is elevated one-half to three-quarters of a centimeter. The interest of these observations lies in its explanation of the cases of heart failure after lumbar puncture. It is observed especially in those whose nervous systems are seriously involved, as in dementia precox. It is much more marked in the aged than in the young, the former having arteriosclerosis. The evacuation of cerebrospinal fluid modifies the circulation, and different organisms react differently to this lowered arterial condition.

Corpulence in Adolescence.

The fat boy has always been an interesting study for the profession and laity alike. Sometimes he is fat in childhood and becomes thin after puberty. Other subjects retain their fat after that period has passed. Still others do not take on fat until puberty; such may remain obese for some years and then manage to lose their adipose by the time they have attained their majority. Cases of each sort will doubtless readily occur in the memory of the seasoned observer. Dr. Stern of New York, well known for his efforts to subdivide obesity into a number of distinct conditions, has written an article on youthful obesity for the *Berliner klinische Wochenschrift,* for July 25. Stern's researches take cognizance of all possible factors in fat metabolism, together with many alterations not usually considered under this head. Thus, he states that in specific obesity fat girls have long and luxurious hair; while in accidental obesity from diet, etc., this feature is not in evidence. Such documents, of course, bear chiefly on the subject of an innate and acquired obesity. Innate obesity naturally runs in families—is a familial affection. Whether surplus fat is inevitable or only accidental Stern is opposed to dietetic restrictions, which may prove an injury to the growing organism. At the same time modification of the diet, along with all other physico-therapeutic measures, must first be tried, and may prevail in accidental cases. If such measures fail he would use an anticorpulence prescription comprised of arsenic (sodium cacodylate), adonidin, and powdered thyroid gland.

The Alleged Mutation Between Gonococci and Trachoma Bodies.

As was to have been foreseen, the claim advanced recently by Herzog that trachoma bodies are only a transmuted form of ordinary gonococci has been answered promptly by Lindner *(Deutsche medizinische Wochenschrift,* July 14), who had recognized the coexistence of two parasitic forms without any intimation as to their ultimate identity. In the short communication by Lindner it does not appear that the theory of Herzog is actively opposed, but rather that certain obstacles must be removed before the theory can hope for recognition. Throughout Herzog is made to refute himself; so that the latter has rather to strengthen his own argument than to meet new obstacles from actively hostile sources. Much stress is laid on Herzog's admission that he could never cultivate gonococci from trachoma in the adult, nor even from the newly born (save in rare cases of probable mixed infection). Lindner is in fact satisfied to let the matter rest here. The footnote appendix of Herzog that he had succeeded at last in producing apparent trachoma bodies by inoculating adult eyes with gonococcus cultures, does not modify Lindner's opinion. Such brief allegations made on going to press naturally require some substantial corroboration. Halberstaedter, who is committed to the theory of the specific nature of the trachoma bodies, writing in the *Berliner klinische Wochenschrift* of August 8, sums up his views of Herzog's mutation theory as follows: Neither the morphological relations of the gonococcus in culture, nor inoculation experiments on apes, nor any findings to date as to our knowledge of trachoma, give us any support in claiming that the gonococcus is a mutation of the chlamydozoa.

News of the Week.

Library of the Academy of Medicine.—The president of the New York Academy of Medicine in a recent letter to the Fellows of the Academy calls attention to the necessity for prompt action in providing for the future growth of the library in particular, and rehearses the steps already taken toward the desired end. The urgency of the need is shown by a report made by the Library Committee last year, in which it was stated that calculations based upon the present available shelf room and the average rate of acquisitions for the last five years indicated that a halt in the activities and growth of the library would result not later than three years from January 1, 1910, even though use were made of various makeshifts. Acting upon this report, the president appointed a committee consisting of the officers of the academy, the ex-presidents, the chairmen of sections, and the members of the Library committee to consider the matter. From this committee in turn a Committee on Site and a Committee on Finance were appointed. The final report of the Committee on Site states that three possibilities for providing the necessary facilities were considered, the first being the enlargement of the present building by new construction from new foundations. After consultation with architects this plan was relinquished as inadvisable. The second possibility was the purchase of property elsewhere and the erection of a new building. This, while it at first met with approval, was finally abandoned because of the almost prohibitive cost of a suitable building, and the loss of facilities during removal. The third possibility was the acquirement of property adjacent to the present building to be used for stack and administration rooms with the idea of rearranging the present building at some later date. This, the most generally acceptable plan, proved also to be the most promising and economical, providing the increase in space without the necessity of removing from the convenient and central location now occupied. The committee was able to secure options on the property at 15 West Forty-third street and at 10 West Forty-fourth street for $120,000. It proposed that a mortgage be raised upon the present building at 4½ per cent. to pay for the new lots. This would entail an expenditure of $6,000 a year for interest and taxes on the two parcels. At a special meeting of the Academy on July 18 it was unanimously voted that the Academy immediately acquire both pieces of property and contracts were accordingly signed on the following day. The Committee on Finance is now planning to raise money by contributions from the members in order to diminish the amount of the proposed mortgage and every member is asked to give his vigorous and loyal support to the movement. For the present the Forty-fourth street property will, as soon as money is forthcoming for the necessary construction, be used for stack rooms, etc., since the lease on the other parcel runs until January 1, 1916. By that time it is hoped that plans will have been approved for a structure to cover the entire property now owned by the Academy, the construction of which can be so carried out as not to interfere with the activities of the Academy.

Efficient Quarantine.—Attention has been again called to the efficient quarantine in force at the Port of New York by the holding up of the S. S. *Lusitania*, which was detained over night until a case of sickness in the steerage could be investigated. Detention of one of the fast Atlantic steamships is not often necessary, and the incident caused much comment. There is but little chance that cholera will reach this country through New York.

New York's Census.—The population of the City of New York is announced officially at 4,766,883, an increase during the last decade of 38.7 per cent. During the previous decade the increase was 37.1 per cent. The largest increase per population was in the Borough of the Bronx, which has enlarged 114.9 per cent. In Brooklyn the increase was 40.1 per cent., and in Manhattan 26 per cent. The following are the figures for the last three counts are as follows::

Population.	1910.	1900.	1890.
New York City	4,766,883	3,437,202	2,507,414
Manhattan Borough	2,331,542	1,850,093	1,441,216
Bronx Borough	430,980	200,507	88,908
Brooklyn Borough	1,634,351	1,166,582	838,547
Richmond Borough	85,969	67,021	51,693
Queens Borough	284,041	152,999	87,050

Red Cross Aids Foresters.—Because men injured in the service of the Government while fighting forest fires in the Northwest cannot receive aid from the Government when their disabilities are so serious as to force them from the payroll, the Red Cross has appropriated the sum of $1,000 to cover hospital expenses in such cases. The money will be used under the direction of one of the assistant foresters for the relief of the civilian fire-fighters, many of whom were forced into the service by law, and for whom no provision is made in case of injury.

Fourth of July Victims.—The carefully compiled statistics of the American Medical Association show that the agitation for a sane Fourth has had some effect, a decrease in the number of victims being particularly notable in those communities which have passed restrictive legislation. The summary shows that this year 2,923 persons were injured, of whom 131 died. In 1903 the injured numbered 4,449, of whom 466 died. The total for the eight years is 37,526 persons injured in Fourth of July celebrations, with 1,662 deaths resulting directly from the injuries and from tetanus following the wounding. The eyesight was destroyed in 122 cases; 551 persons lost the use of one eye, and 432 were crippled by the loss of arms, hands, or legs, and 1,541 by the loss of fingers. The greatest reform was accomplished this year in Massachusetts where the injuries were only one-seventh of the number for the previous year. Missouri, New Jersey, and New York reduced their injuries to one-third, while the totals in Indiana, Iowa, and Wisconsin were larger than those of a year ago.

"Soothing Syrups" Barred.—The Philadelphia Association of Retail Druggists at a recent meeting adopted a resolution binding its members to discourage the sale of the class of preparations known as "soothing syrups," designed for the use of infants and containing habit-forming drugs.

Porous Plasters and Diplomacy.—The German Government has announced that, in accordance with the request of the United States Government, the tariff on porous plasters imported from this country into Germany has been reduced. The State Department last winter in the course of tariff negotiations called attention to the unfavorable treatment to which porous plasters manufactured by American firms were subject upon importation into Germany. They were then classified as "secret reme-

dies," and required to pay a duty ten times as high as that considered proper. The classification of the product has now been changed, and the tariff reduced accordingly.

Yonkers Hospital.—The North End Improvement Association of Yonkers, New York, has declared its intention of bringing before Governor Hughes the alleged unsanitary condition of the building used for the treatment of contagious diseases in that city. The association asserts that the hospital is a menace to health rather than a benefit.

"A Million for Tuberculosis."—This is the slogan adopted in connection with the sale of the Red Cross Christmas seals for 1910. The National Association for the Study and Prevention of Tuberculosis will cooperate with the Red Cross this year in the sale of the seals and will share in the proceeds. Because of criticisms of the use of the word "stamp," the stickers will be called seals and will be used on the backs of letters.

Leland Stanford Medical School.—Several additions are being made to the medical school at Leland Stanford University. Last year one wing of the museum building was set aside for the use of the Department of Anatomy under Prof. A. W. Meyer, and this year two other wings will be used. One will be used by the Department of Bacteriology under Prof. Hans Zinsser, formerly of the College of Physicians and Surgeons, New York, and the other will house the Department of Pharmacology, the head of which is Dr. Albert C. Crawford, until recently connected with the Bureau of Animal Industry. Both Dr. Zinsser and Dr. Crawford are recent appointees to the medical faculty.

Civil Service Examination.—The United States Civil Service Commission announces an examination to be held on September 14 to secure physicians to fill the following vacancies: One at Cahuilla, California; one at Pueblo Bonita, New Mexico; one at Santa Fe, New Mexico; one at Western Shoshone, Nevada, and one at White Earth, Minnesota. These positions pay $1,000 a year each, and are open only to men physicians between the ages of twenty and forty. Further information may be obtained from the United States Civil Service Commission, Washington, D. C.

Acute Poliomyelitis in Pennsylvania.—According to figures compiled by Dr. Samuel G. Dixon, Pennsylvania State Commissioner of Health, 443 cases of acute poliomyelitis were reported in forty counties of the State during the month of August. One hundred cases were reported from Northampton County, 96 from Lancaster County, 68 from Philadelphia County, and 52 from Lehigh County.

Typhoid Fever in Philadelphia.—For the week ended September 2 73 cases of typhoid fever were reported to the Philadelphia Bureau of Health. Many of these, it is believed, were acquired by persons while in the enjoyment of vacations out of the city.

Charitable Bequests.—By the will of the late Mr. Max Bamberger of Philadelphia, who died recently in Kissingen, Germany, the Jewish Hospital Association of Philadelphia receives $10,000, and $5,000 each is left to the following institutions of that city. Mt. Sinai Hospital, Jewish Maternity Hospital, Hebrew Orphans' Home, and Jewish Foster Home. The Jewish Hospital for Consumptives, Denver, Col., also receives $5,000. The residuary estate, estimated to be about $400,000, is to be used in erecting and maintaining a seaside home for Jewish children at Atlantic City, to be known as the Max Bamberger Seashore Home.

International Congress on School Hygiene.—The next meeting of the Congress is scheduled to be held in 1913 at Buffalo, N. Y.

The Michigan State Medical Society.—The annual meeting of this society will be held at Bay City on Wednesday and Thursday, September 28 and 29. Dr. George W. Crile of Cleveland will make the scientific address at the opening session.

The International Medical Association for the Prevention of War.—The organization of a society of medical men under the above title has recently been suggested, and an executive committee has been formed, Dr. J. Riviere of Paris being at its head. It is hoped that a congress may be held in Paris some time in 1911. In this country the association is represented among others by Dr. W. B. Snow of 329 West Fifty-seventh street, New York, and Dr. George Brown of Atlanta, Ga.

American Electro-Therapeutic Association.—The twentieth annual convention of this association will be held at Saratoga Springs, N. Y., September 13, 14, and 15, 1910. A full program of committee reports and papers on subjects relating to physical and electro-therapeutics has been arranged, and much serious work has been done in a determined effort to place work in the field of physical therapeutics on an exact scientific basis. There will be an accompanying exhibition of electrical apparatus. The medical profession is invited to attend. Headquarters will be at the United States Hotel. Assembly and exhibition halls are at the Hathorn Spring Building. The president of the Association is Dr. T. D. Crothers of Hartford; the secretary is Dr. J. Willard Travell, 27 East Eleventh street, New York City.

Association des Médecins de Langue Francaise de l'Amérique du Nord.—At the closing session of the fifth congress of this association, held on August 25, the following officers were elected: *Honorary Presidents,* Drs. J. J. Guerin and P. V. Faucher of Montreal; *President,* Dr. Henri Hervieux of Montreal; *Vice-Presidents,* Dr. A. Rousseau of Quebec, Dr. J. O. Ledoux of Sherbrooke, and Dr. Gauthier of Upton; *Secretary,* Dr. E. P. Chagnon of Montreal; *Treasurer,* Dr. B. C. Bourgeois of Montreal.

Dr. S. Nagayo of Tokyo died on Monday of this week. He was president of the Japanese Society for Gastroenteric Diseases, editor of the *Archives of Digestive Disorders,* a monthly journal in the Japanese language, and director of a sanatorium for the treatment of diseases of the stomach. Dr. Nagayo was chiefly instrumental in establishing the specialty of gastroenteric diseases in Japan, and labored in many other ways to advance the cause of scientific medicine in his country. In his death Japanese medicine suffers an irreparable loss.

Obituary Notes.—Dr. Harry Vroom Day of Butler, N. J., a graduate of the Medical Department of New York University in 1877, a member of the New Jersey State and Butler County Medical societies, died recently of cancer at his home, aged 57 years.

Dr. Francis Hart Stuart of Brooklyn, N. Y., died September 4 of heart disease. He was born in Logansport, Ind., and was graduated from the Long Island College Hospital in 1873. He was a

member of the American Medical Association, American Academy Medical and British Medical Associations, Brooklyn Pathological Society Obstet., Brooklyn Hospital, consulting physician of the Samaritan Hospital, and the University Club of the city of his residence. Of a busy temperament, with devotion to his duties, he made a reputation for himself as a clinical lecturer to students at the leading hospitals.

Dr. SAMUEL C. JOHNSON of Sharon, Pa., a graduate of the Jefferson Medical College of Philadelphia in 1879, died suddenly on August 28 while attending a patient.

Dr. ALPHONSE WETMORE of Clinton, Ia., a graduate of the Medical Department of New York University in 1848, died at his home on August 24, aged 90 years.

Dr. WALTER F. ATLEE of Philadelphia, a son of Dr. John L. Atlee, the distinguished surgeon of Lancaster, Pa., a graduate of Yale University in 1845, and of the Medical Department of the University of Pennsylvania in 1850, died at his home on August 19, aged 82 years.

Dr. JOSEPH A. SCROGGS of Keokuk, Ia., a graduate of the Rush Medical College, Chicago, and a member of the American Medical Association, the Iowa State Medical Society, and the State Board of Health, died at his home on August 24 of diabetic gangrene, aged 62 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

DENTAL AND MEDICAL REFORM—WHOOPING COUGH—BACILLURIA IN CHILDREN—LUNACY REPORT—ROYAL COLLEGE SURGEONS' MUSEUM—FAITH HEALING AND AN INQUEST—DOCTOR AND GUARDIAN'S DUTIES IN SCHOOL EXAMINATIONS—OBITUARY.

LONDON, August 19, 1910.

"Is it reasonable to suppose that an unqualified operator can by actual practice and experience ever acquire the knowledge and skill of the qualified dentist?" This is the question put in a leading article of *M. A. P.*, the enterprising journal so entitled, interpreted as "mainly about people." The question applies just as much to medicine and surgery, in fact, to the whole medical art, as to the dental branch. But just now this branch is prominently before the public in consequence of recent proceedings, and the leaders are more alive to the importance of further protective legislation than those of the profession as a whole. *M. A. P.* proceeds to demonstrate the danger to the public of permitting unqualified dentists to practice, dividing these persons into: (1) Honest and fairly competent; (2) honest, but incompetent; (3) unscrupulous or incompetent; (4) rank swindlers. The first class seems scarcely admissible, according to the subsequent logical statements of the article, for the writer sets out that there may be here and there a man whose lack of means prevented him after two or three years completing his training. But, he adds, "after all, why should they be allowed to practice?" And further, he continues, "a solicitous clerk may have passed all the necessary examinations, but is debarred from practice until his name has been enrolled."

I am citing a journal extensively read by society rather than our professional organs, as it indicates that the question of illegal practice has not been allowed to rest by the dentists, and so they have secured more attention than the doctors for their legislative demands. The medical journals have, of course, constantly advocated protection from quackery of all kinds. The *Medical Press and Circular* has been prominent in defense of the dental branch. The current number of the *Lancet* contains a letter from Mr. Morten Smale, who has long held the highest position among dental surgeons, is consulting surgeon to St. Mary's Hospital, the Royal Dental Hospital, dean of the school, and examiner at the Royal College of Surgeons, of which he is a member as well as dental licentiate. His wider experience convinces him that a new act must be obtained absolutely restricting practice to registered persons and containing a penal clause so worded as to prove effectual. He would, however, in order to pass the act more easily, I suppose, suffer existing unqualified ones to continue in practice if they can show some competence on examination. On this point I would refer him to the logic of *M. A. P.* As to a perfect penal clause I almost despair of the parliamentary draftsmen being able to frame one. Irregular practitioners will not call themselves dentists or similar terms. Only this week I passed in one suburb four brass plates inscribed "Mr. ——, artificial teeth." Need I say what that implies?

Whooping cough should lose most of its terrors if Dr. Essex Wynter's statements at the Children's Section of the Medical Association should be fully confirmed. It is true that many poor people let it run its course from a prejudice that nothing does any good, but they would be glad enough to see their children rapidly cured. Chloretone (2½ grains three or four times a day) is Dr. Wynter's remedy, and the paroxysms, he said, were practically subdued in three days. Dr. Zangger had contributed a paper on this disease in which he had spoken of it as a contagious disease of bacillary origin with reflex nervous symptoms. To meet the infection he gave quinine hydrochlorate. Next in efficacy he found euquinine, which is but slightly bitter and does not irritate the stomach. For the nervous complication he advised packs to the trunk at 52 to 60 deg. F. for one to four hours—a very powerful nerve sedative they proved. He had treated some 200 cases in the course of practice, and in severe cases the convulsive stage had been reduced to 20, 15, or sometimes 10 days. It was rare to have more than twenty paroxysms of coughing in the twenty-four hours under this treatment, and they diminished from day to day in number and also in intensity. He had no deaths and no complications. Yet it was after hearing this paper that Dr. Wynter made the statement I have quoted and congratulated Dr. Zangger.

At this meeting the set discussion was on infection of the urinary tract in children by bacillus coli. It was opened by Dr. Box, who said the condition might be acute or chronic. Other organisms were sometimes found, but the *B. coli* was most common. Occasionally they might excite few or no symptoms, but generally produced some inflammation of the mucous lining of the tract. This was frequently confined to the bladder, but might extend upwards. In such cases there would be feverishness of a typhoid type, preceded perhaps by rigor or convulsions. Tenderness over the region affected would occur, but diagnosis must rest on the presence of the bacilli in the urine, which was usually highly acid. For treatment its acidity should be neutralized, and it should be diluted by free drinking. He gave potass. citrate enough to keep the urine alkaline. Dr. Pardoe said he trusted rest in bed on milk diet, with diluents, alkalies, and sandal-wood oil as an antiseptic. Dr. Parkinson had seen improvement after injections of dead bacilli. Dr. Cautley said bacilli might abound in the urine without setting up symptoms, and he had little faith in drugs, though benzoates seemed to have some effect. Other speakers referred to the obstinacy of chronic cases, the want of uniformity in the organisms (various strains of the *B. coli* being found). One gave urotropin for weeks. Another observed that the *B. coli* grew in an alkaline fluid, but that increased phagocytosis, and so might be beneficial. The fact that *B. coli* is met with in other diseases (diphtheria and scarlatina) was also mentioned, as was a case treated by potass. citr. per rectum, with rest and milk diet.

The report of the Lunacy Commissioners shows, for the year up to January 1 last, a further increase of certified insane persons. But the increase is below that of the annual average during the decennium. It is also lower than any yearly increase since 1901. Some curious notes can be picked out from the tables, *e.g.* from that about occupation it appears that in those classed as professionals teachers furnish the lowest rate, viz., 7.9, but physicians have a rate of 12.9 per 10,000, lawyers 15.2, clergy 13.1. As to causes the commissioners consider the figures point in both sexes to an association of heredity with the insanity of adolescence, with that of mental stress, and that of influenza; in males with addiction to alcohol; in females with puerperal insanity and with epilepsy.

Prof. Arthur Keith, the Conservator of the Hunterian Museum, has issued an illustrated guide to this great collection, in which, as he says, the animal kingdom has been "ransacked" to show the meaning of its structure and working. The pathological department occupies a good deal of space in the book, and includes the recently acquired Nubian collection. Some of the exhibits have an interest outside the medical art, *e.g.* a cast of Livingstone's

broken arm which was crushed by a lion and a rib of Robert the Bruce showing a fracture, united. There is also in the guide a short history of the museum, always of interest. Dr. Wm. Hunter's anatomical school was a very important institution in the middle of the eighteenth century, and in that his brother John qualified and assisted in the demonstrations—later serving for a time as surgeon in the army. In 1763 he retired from the army and began practice in London, collecting specimens which interested him. In 1783 John Hunter bought two houses and built a museum for his collection, on which he spent his whole fortune, which before he died was some £70,000. When the British Government bought it they only paid £15,000 for it, and handed it over to the care of the Royal College of Surgeons. A further sum of £42,500 has since been contributed by the government towards the building of the present museum, which with its contents is estimated to have cost upwards of £500,000, mostly provided by the college.

A case of faith healing which did not heal has ended at Nottingham in an inquest on a body of a woman of fifty-eight who was said to be confined to bed for nearly three years without medical aid. The only other occupant of the house when she died said the deceased had a dislike to doctors, and had suffered from much pain and laid in one position all the time. She relied on faith healing. A medical witness said that when he called he could not persuade the occupants she was dead, as they told him "God had assured her she was not going to die." The jury returned a verdict of death from blood poisoning from self neglect, and censured two witnesses who had lived with the deceased.

The local government board has issued its conclusions on an inquiry respecting differences between Dr. Ross and the Brighton guardians. The doctor, they find, acted improperly in arranging for the transfer of some children from the schools to the workhouse infirmary in disregard of the views of the guardians. If he considered the resolution of the guardians detrimental to the children he should have made formal representation in writing to that effect. Still it is admitted children with serious illness in need of special treatment and continuous observation would be better in the infirmary, where there is a resident medical officer. A weekly examination of all the children is not necessary. A monthly inspection should insure detection of contagious diseases. A detailed examination of each child in apparent health need only be made at occasional intervals.

The death is reported of Mr. Robert Wm. Coe, at the age of eighty-eight, who was admitted a member of the Royal College of Surgeons in 1844 and to the Fellowship in 1852. He was for years lecturer on surgery at the Bristol Medical School, surgeon to the General Hospital, the Children's Hospital, and Lock Hospital. In due course consulting surgeon. He contributed some interesting articles to the journals and societies.

Dr. Frederick Weatherley, J.P., of Portishead has died at the age of ninety. His College and Hall diplomas are dated 1841. He was formerly surgeon-major in the volunteers artillery.

Dr. J. T. Faulkner, a distinguished Owen College man and M.D. Lond., has died quite suddenly, at the age of fifty-four, after attending a political demonstration and later joining in a dance.

It is sad to have to report such a tragedy as the death at the hands of his son of Dr. James Hamilton Nicholas, a retired major in the Royal Army Medical Corps. There seems to be little doubt that the son was insane. Meantime a coroner's jury has returned a verdict of murder, and the consequent measures will be taken.

Dr. Wm. P. Counsellor has died at Weymouth, at sixty-three. He practised for many years at Manchester, and had been M.O.H. in the Lancashire Rural District. He was M.R.C.S. 1873 and M.D., Durham, 1887.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 25, 1910.

Lactic Acid Bacteria: What They Are and What They Are Supposed to Do.—Arthur I. Kendall states that in the restricted sense in which the term "lactic acid bacilli" is used in intestinal therapeutics only those organisms are regarded as true lactic acid bacteria which form lactic acid and smaller amounts of lower fatty acids, but which do not form putrefactive products from protein, and which do not produce gaseous products from the fermentation of carbohydrate. In addition to the proteolytic bacteria and the fermentative bacilli of the lactic acid type, there is a third group of intestinal organisms which is facultative with respect to protein and carbohydrate requirements. This facultative group is by far the largest of the three groups, and includes many of the best known of the intestinal flora, of which the *Bacillus coli* is an example. The effects of lactic acid therapy are summarized as follows: (1) Objectionable proteolytic activity, resulting in the absorption of a host of aromatic substances derived from protein decomposition by the action of proteolytic bacteria, may take place in the intestinal tract. (2) These aromatic compounds may be formed in the small or large intestine by the facultative or obligate proteolytic organisms. (3) The excess of protein in the diet of the host, or any factor causing stasis or impaired absorption of protein, appears to be the direct cause of this condition. The result is an unusual amount of available food which stimulates the development of these proteolytic intestinal organisms. (4) The addition to the diet of easily fermentable carbohydrate, together with the restriction of the protein, is of material assistance in reducing the output of these putrefactive products in many instances. (5) The beneficial action of the carbohydrate is twofold: First, the character of the metabolism of the facultative organisms tends to change from the putrefactive to the fermentative type, eliminating by the urine the putrefactive products referable to their activity; and, second, the lactic acid bacilli, either those given by the mouth or those normally present in the intestinal canal, or both, proliferate rapidly, forming considerable amounts of lactic acid and inhibit the further development of the obligate proteolytic organisms by rendering the medium in which they are growing unsuitable for continued development. (6) The proteolytic bacteria may be producing their harmful effects either in the small or large intestine; in the former case the introduction of the organisms of the bulgarian type may reasonably be expected to be of some benefit. If the proteolytic process is of the large intestinal origin, the normal lactic acid bacilli of the acidophilus type are indicated. If there is reason to suspect that these normal intestinal lactic acid bacilli are enfeebled or absent, it will be necessary to introduce fresh cultures by the mouth or the rectum. (7) While the primary object of introducing lactic acid bacilli is to inhibit the objectionable activity of proteolytic organisms, experiments seem to indicate that, in addition to the formation of lactic acid, other products associated with their development may be formed which also act beneficially. The nature of these products and the character of their action is not definitely known.

New York Medical Journal, August 27, 1910.

Oral Prophylaxis.—L. Ashley Faught says that it is freely conceded that the mouth and teeth should be kept clean, that neglect hurts the teeth and gums, and, ultimately, the general health; and patients are yet too frequently dismissed with some general advice about brushes, floss silk, and dentifrices, and as a result the hygienic care by the patient falls short between visits to the dentist. The object of this paper is to awaken both dentist and physician to a more serious view of the great importance of oral prophylaxis. Patients need to be instructed as to the importance of the active use of the teeth; they are the organs of mastication, and should be so used; that use means health. The teeth should be brushed on the lingual and palatal surfaces, as well as on the buccal and labial sides, with a rotary motion of the brush, brushing the gum as well as the teeth, from the gum toward the crowns of the teeth; not with a rotary motion in that direction and then in the reverse direction, but with a movement which shall be peculiarly always in the one direction only, the direction of tooth growth; the motion to follow the axis of the tooth, giving particular attention to the inside of the lower arch in the molar region. Great care should be taken to reach all the surfaces of the teeth situated well back in the rear of the mouth. The teeth should also be brushed backward and forward on the occlusal or chewing surfaces. During the brushing from time to time the mouth is to be rinsed with an antiseptic solution. Waxed floss silk should also be used by passing it between the teeth. This attention, after each meal and before retiring, should be sedulously given.

Hypothyroidism.—Robert L. Pitfield says this is a commonly overlooked disease; hypothyroidism may be so mild as to cause a few pains and aches, or so severe as to render the victim a bedridden invalid, ugly, perhaps, and miserable; and often a complete puzzle for the medical attendant. Not always is the patient myxedematous. He has seen nine cases, all in children; all had joint pains that were called rheumatism. The fat ones were thought to have Bright's disease, the thin ones nervous prostration. All had their ills wrongly diagnosed. He believes that this disease

should be classed among the nervous diseases, and not among those of the ductless glands. He reports four cases, two of them exhibiting the rarer symptoms of this disease; one was the premature menopause and the other synovitis of the knee. The patients were all neurasthenic. The relief afforded by thyroid is another prop to support the doctrine that neurasthenia is very rarely a primary disease.

Anemic Ulcers of the Throat.—Albert G. Pohly says that ulcers of the throat are either due to tuberculosis, syphilis, or angina Vincenti. He reports in detail three cases which were due in all probability to anemia. The ulcers in these cases are small, round, with a scanty secretion. These occurred in young women, and there was no history of either tuberculosis or syphilis. There was no glandular swelling.

Journal of the American Medical Association, August 27, 1910.

A Possible Differential Sign Between Cardiac Dilatation and Pericarditis with Effusion.—W. J. Calvert says that extreme dilatation of the heart is often difficult or impossible to differentiate from large pericardial effusions, and he gives a possible differential sign. In patients with large hearts the sternum is depressed, the entire liver is depressed, the right lobe of the liver is relatively elevated as to interspaces, the right lung is elevated and pushed outward and backward, thus giving a high position of the liver with a narrow band of lung-liver relative dullness. In pericarditis with effusion the liver is depressed, the right lung is pushed outward and backward more than upward, thus giving a low position of the liver with a narrow band of lung-liver relative dullness. The size of the liver is of no material importance. Two factors compose the differential sign—the position of the liver and the presence and position of the diminished area of lung-liver relative dullness. Of these the position of the liver is most important.

Neuralgias and Functional Disturbances Arising from Infections in and About the Tonsil.—Frank C. Todd emphasizes the following points in concluding his paper: 1. Pain and soreness in the neck in the region of the tonsils usually arise from diseased tonsils. 2. Neuralgias in the region of the tonsil, ear, side of head, neck, nose, teeth, gums, or antrum of Highmore, may be and frequently are caused by diseased tonsils. 3. Disturbances of function through pressure on or inflammation of nerves may manifest itself in hoarseness, in loss of voice, cough, difficult deglutition, or entrance of food into trachea, with regurgitation; or in defects in hearing, dyspepsia, and disturbed heart action. 4. Such diseased tonsils may not be and usually are not large or acutely inflamed. They must be carefully examined by the surgeon, who should pull them into view with a dull hook, determine whether the crypts contain detritus, whether the tonsils are sore to such manipulation, bleed easily, or otherwise give evidence of being diseased. 5. Such tonsils should be carefully and completely removed. 6. Relief of secondary infections usually follows immediately on removal, but sometimes only slowly if neuritis or secondary glandular involvement is present. 7. In certain cases paralysis may be permanent.

The Rôle of Surgery in Preventive Medicine.—Miles F. Porter suggests that by the removal of infection atria surgery may do much to prevent disease. That adenoids and diseased tonsils and gums are the port of entry for many serious infections is well recognized, but the etiological relationship that these conditions seem to bear to rare infections, such as noma and acute poliomyelitis, should also be considered. The removal of such deformities as club-foot hernia, etc., not only makes it possible for their possessors to lead much more hygienic lives, which conduces to greater physical strength, but effects a psychic improvement in such cases which is quite as important. All suppurating lesions and local tuberculous lesions should be treated not only in the interests of the patients themselves, but in the interests of the community. Deaths from brain abscess, meningitis, and thrombophlebitis, resulting from neglected middle ear disease, are all too common. By removing causes of irritation in the shape of gastric ulcers, lacerated cervices, phimoses, gallstones, kidney stones, warts, moles, and other nonmalignant tumors and causes of irritation, surgery can prevent more deaths from cancer than it can by the removal of cancerous conditions after such a diagnosis is possible. The writer quotes from authorities to show that the consensus of opinion favors cesarean section as giving better chances of life and health to both mother and child than can be claimed for ordinary obstetrical operations in the same class.

A Cutaneous Anaphylactic Reaction as a Contraindication to the Administration of Antitoxin.—W. L. Moss, believing that it would be desirable to determine in advance those cases in which a second administration of serum will precipitate dangerous anaphylactic manifestations, has made the following test in thirty cases. The skin of the inner side of the upper arm is cleansed with alcohol and dried with a sterile sponge, and 0.01 c.c. normal horse serum is injected intradermally. A positive reaction consists of an area of inflammation 1 to 2 cm. in diameter, which comes on within twenty-four hours and disappears in two or three days. The entire reaction is sometimes over within twenty-four hours, so that an observation should be made ten hours after the injection. The reaction is purely local. Of the thirty individuals tested nine had never received any form of antitoxin, and results were all negative; the remaining twenty-one had received antitoxin from four months to ten years previously. Ten of these gave positive reactions and eleven negative. The results did not seem to depend on the length of time that had elapsed since former injections. Of the ten positive reactions three gave much more marked reactions than the others, and it seemed possible that reactions of this nature might indicate danger from any further injection of antitoxin serum. The value of this test can be determined only by injecting therapeutic doses of antitoxin in individuals who give a positive skin reaction. Dr. Moss urges that where opportunities offer further investigations be made to determine the value of this test, as a means of knowing in advance those cases in which a second injection of antitoxin are contraindicated, and thereby preventing the lamentable accidents which sometimes now occur.

The Lancet, August 20, 1910.

A Case of Migraine Associated with Chlorine Retention.—Hubert Higgins bases this paper on records of observations made in a case of long-standing neurasthenia and migraine in a man aged forty-three years. The chief subjective sensations complained of were those of exaggerated fatigue, mental depression of an overwhelming, unreasoning kind, and headaches lasting as long as three days at a time, accompanied by the usual migraine symptoms. These symptoms were invariably and quickly removed by means of not more than seventy drops of phosphoric acid. On each occasion there was decided increase of indican. The main indications, as revealed by urinary analyses, were to secure dechlorination by as simple means as possible, and to administer magnesium, calcium, and phosphorus in the form of eggs. It was clear that the full remineralization ration (earthy and vegetable salts in addition to eggs and meat) produced too great a reaction, as it changed the day by night quotient from 1.1 to 0.7 in the case of urea, and from 1.0 to 0.6 in the case of uric acid. During the remainder of the time that the patient was under observation he was allowed rather more than his ordinary ration without vegetable salts. For twenty-three days out of forty-four there was a rigid chlorine free diet; on the other days he partook of the usual hotel fare, not adding any salt to it. Allowing a liberal estimate for salt used in cooking, while the patient was on ordinary diet, the total dechlorination was 309.63 grams. The permeability tests showed that there was no evidence of renal inadequacy. In this case the force which retained the chlorides in the tissues must necessarily operate in the cells themselves, and it was reasonable to conclude that retention was present in order to maintain the balance between colloids and crystalloids. The urea and uric acid analyses the author took as being an indication that the tissues reacted too strongly to the meat, and that in cases showing such an extreme reaction the meat ration should be reduced to a minimum and the proteid ration as well to half the normal quantity. During observations in this case the blood pressure had risen to 95 millimeters, and hence only 0.5 gram of calcium carbonate was given. This was increased or diminished according as the blood pressure rose or fell. Two grams of hydrate of magnesium and a small ration of iodine in combination were also given. The author urges the necessity of seeking out and demonstrating to cases of this class the physical causes of the psychical phenomena.

A Case of Rheumatic Arthritis Followed by Streptococcus Invasion.—G. R. Strong reports the case of a girl twenty-one years of age, who gave a history of an attack of tonsillitis and other symptoms which indicated that she was suffering from an attack of acute rheumatism, but against this was set a history of pain in the soles of the feet and lumbar fascia, the absence of cardiac signs and a characteristic appearance of the left wrist, which suggested gonococcic arthritis. Examination of fluid aspirated from the wrist and of a swab from the vagina failed to show

the presence of the gonococci. During the course of her illness the reaction to the salicylates left no doubt but that the case was one of acute rheumatism. Seventeen days after her admission to the hospital her temperature suddenly rose to 104° and she complained of sore throat, and a faint erythematous rash appeared on her chest and abdomen. Scarlet fever was suspected. A swab taken from her throat yielded streptococci and staphylococci. The urine was found to contain casts and much free blood and leucocytes. She now has a systolic murmur at the apex. Her condition immediately became grave and she died four days after the onset of these symptoms. The appearances at the autopsy were those of an intense septicemia and pneumonia. Death had occurred from toxemia. The pus from the pleura contained many streptococci. Sections of the lungs showed appearance of intense inflammation but not just that of pneumonia. The kidneys were enlarged, engorged, and bled on section. The points of interest in this case are: In the first place, was the illness of which the patient died a streptococcic infection or a very severe attack of scarlef fever? A streptococcus being frequently found in association with this disease is believed by some to be the actual cause of it. Where is the line to be drawn between scarlatina and streptococcic septicemia? Secondly, was the fatal illness a new infection or merely a relapse in the course of the disease from which the patient was suffering when admitted? The writer was inclined to the former view. Another point of interest was the pneumonia which was evidently only a part of the general infection.

A Note on the Abuse of Purgatives.—Herbert French thinks that in the recent discussion upon the treatment of constipation at the meeting of the British Medical Association it was not clearly brought out that a great deal of chronic constipation is actually due to the abuse, that is to say the injudicious use of purgatives during the preceding years. Even laxatives ought seldom be used, and then only with the greatest caution. The habitual use of laxatives during adolescence usually necessitates the resort to purgatives in early adult life, and as years go on stronger and stronger remedies become necessary, until none has the desired action. Instead of encouraging Nature's tendency to act once a day the use of a purgative forces the bowel periodically and leaves it inactive in the interval. There is no doubt that a great deal of the chronic constipation of to-day is due to deficiency of exercise and to the removal from our dietaries of many things which, being indigestible, used to pass through and increase the bulk of the residue. This constipation is accentuated by the abuse of purgatives. By the term indigestible we understand not a substance which produces indigestion but one which passes through the alimentary canal undigested, as the fiber of green vegetables and fruits and portions of husks in porridge and brown bread.

British Medical Journal, August 20, 1910.

The After-History of Forty Cases of Epithelioma of the Lip.—A. Rendle Short classified these cases according to the method of operation adopted. Of twenty-three cases where only one operation was performed and the growth removed by a V-shaped incision, the glands not being removed, fourteen cases are now well, four are known to have died of recurrence, two more have probably done so, and three have been lost sight of. In six cases where there was one operation only for the removal of the growth on the lip and of a palpable gland or glands, one case is probably cured, three died of recurrence, and two cannot be traced. Of three cases where there was removal of the growth and a complete clearance of all the submaxillary glands at the same time or soon after (although not palpably enlarged) two cases are well and one recurred. Of seven recurring cases operated on more than once, two are well, one has probably recurred, one patient died of pneumonia without recurrence, and three died of recurrence. The author concludes that when the glands are already infected only an extensive dissection will give the patient a reasonable chance of cure. He thinks that this extensive dissection ought to be carried out, even when the growth is small and no glands are palpable. The risk of the operation is not as great as the danger from recurrences. The lesson that a study of these cases teaches is that if the neck is to be cleared it must be done very thoroughly.

An Immense Renal Calculus.—George W. Ord relates the history of this case, which covers twenty years. The case is unusual because of the presence of calculi in both kidneys, the size of the large calculus, the comparatively small amount of discomfort and pain considering the size and irregularity of the stone, the extremely healthy appearance of both kidneys at the time of operation, and the separation of the calculus into two large and one small fragments. The calculi were removed from both kidneys at two separate operations. Those from the right kidney weighed 118 grams, had no nucleus, were bistre in color, easily friable and porous, with rough surfaces. The largest measured 3½ inches by 2 by 2 inches, and had been fractured about its middle some time previously, and a regular articulation had resulted, somewhat resembling an infant's kneejoint, patella included. The calculi were composed of calcium, sodium, and magnesium phosphate and carbonate. The calculi from the left kidney weighed 14½ grams. About two years and a half after these two operations the patient was again operated on, a right lumbar nephrolithotomy being done, and a short time after the right kidney was drained for intermittent hydronephrosis. The patient aborted about a month after this operation and died three months later.

A Simple Method of Removing Sebaceous Cysts.—H. Freeth describes the method which he uses, and which he considers more satisfactory than that in ordinary use. An incision is made, not over the cyst, but through healthy skin alongside it, parallel to and the same length as the shortest diameter of the cyst. The injection of a little eucaine solution along the line of the incision is all the anesthetic required. A small, blunt hook is then inserted into the incision and is worked around the cyst, tearing through the adhesions of the cyst wall, first on the superficial aspect, as that is where the cyst wall is the thinnest, and then on the deeper aspect, until the cyst is completely separated, when it can be delivered by pressure from above. A little collodion on the wound is all the dressing required. The advantages of this method are that the incision is through healthy skin, and where the cyst is oblong is shorter than the usual incision. Consequently, the union is quicker and more satisfactory and the appearance of the resulting scar better than when the incision is made through the altered skin over the cyst. A minimum amount of anesthetic is used, and in case the cyst is situated on the scalp very much less hair need be cut. The largest cyst that Dr. Freeth has removed in this way is about the size of a bantam's egg, but he would employ the same method in removing a very much larger one.

Berliner klinische Wochenschrift, August 8, 1910.

Significance of Ehrlich's Arsenobenzol Remedy in the Treatment of Syphilis.—Neisser and Kuznitzky, after praising the advantages of "606," go quite extensively into the subject of collateral effects. These are divided into local and general. Any unpleasant local effects are naturally avoided by using the intravenous injection. In intramuscular and subcutaneous injections a step forward has been taken by using the remedy in suspension in place of solution [the work of L. Michaelis and Wechselmann in this field is described; both the papers have been given in summary in previous numbers of the MEDICAL RECORD.—Ed.]. Under the intravenous method numerous collateral effects have been recorded, chiefly chills, fever, and vomiting. These symptoms are transitory and leave the patient intact. No arsenic has as yet been found in the vomitus. The temperature in these cases has often been high (up to 40° C.); and on one occasion herpes febrilis developed. That such effects are by no means attributable to the sudden introduction of an alien substance into the circulation is evident from the fact that similar symptoms have followed intramuscular injections; and then very promptly. The authors are inclined to the belief that all such manifestations, however produced, are due to the liberation of syphilitic endotoxins as a result of the sudden destruction of the spirochetes. The chief support for this belief is the fact that these toxigenic symptoms occur in active, but not in latent syphilis. The authors go extensively into our older knowledge of the symptomatology of sudden liberation of endotoxins as a result of mercurial treatment. This subject has a considerable literature. To come back to the new therapy, the authors conceive this to be indicated: (1) In all quite recent cases, in the hope of cure at a single stroke; (2) in any case which does not respond to mercury, and finally (3) in cases overtreated with mercury. A separate section should be made of parasyphilis. We do not of course know as yet whether "606" can prevent paresis and tabes dorsalis, but there is certainly no objection to its use as far as the former condition is concerned. It may be otherwise with tabes, in which the patient is perhaps preordained to opticus atrophy. This possibility can at present only be hinted at.

Pseudoapical Murmurs.—Allard writes very briefly

upon this very important subject, which is so deeply concerned with hasty diagnosis of incipient pulmonary tuberculosis. The author is a member of Prof. Minkowski's staff at the Breslau University Medical Clinic. Given that we obtain in a particular case auscultatory and percutory evidences of incipient phthisis, the question which arises concerns the negative interpretation of the phenomena. No doubt many murmurs heard in these examinations are extrapulmonary and due to contractions of the trapezius, scaleni, etc. Such auscultatory illusions should be corrected by percutory evidence. But all such sounds are not muscular in origin; for in some cases there is evidence that they proceed from a sort of creaking of the bones and joints. The late Dr. Rosenbach was active in this diagnostic field and laid down rules for distinguishing between pulmonary râles and muscular sounds. But the very pains he took with this subject illustrates its intrinsic difficulties. He, as well as others—including the author—sought to exclude muscular participation by a system of "holding" during which auscultation of the apices was being undertaken. No doubt in all routine examinations much can be effected by placing all the muscles concerned in a state of repose.

Münchener medizinische Wochenschrift, August 9, 1910.

Pancreas Intoxication.—Bergmann and Guleke have investigated the subject of systemic autointoxication from the pancreas, which has apparently been suggested in part from the fact that in aseptic autolysis of this gland certain toxins are formed; but more particularly from the pathological finding that in destructive disease of the organ certain fatal toxic phenomena are produced. The toxic action noted in any case is somewhat of the nature of trypsin poisoning, and may be antagonized in experiment by previous immunization with trypsin. Yet these toxic effects cannot be set down necessarily either to trypsin or any other individual enzyme when acting alone; that is to say, the picture differs in some respects from that produced by the injection of commercial trypsin into the blood. Another toxin is present, and this is believed in some quarters to be the digestive product of the pancreatic lipase. The rôle of this element in the intoxication is somewhat complex and is believed to represent a displacement in the blood of its calcium ions as a result of formation and absorption of the very soluble sodium soaps, which are formed from lipase digestion. While experimental trypsin death is said to represent a paralysis of the respiratory center, soap poisoning, when carried out experimentally, represents an acute cardiac death. In pancreas intoxication, however interpreted, we thus have two quite different lethal factors which act in conjunction. So many disease phenomena are nowadays explained by some sort of interference with soluble calcium ions that the refusal of the authors to commit themselves to any definite conclusions need occasion no surprise.

Treatment of Sciatica with Epidural Injections.—Blum refers by the term epidural injection to the anesthetization of the sacral nerve roots after they have left the cord, a resource for local analgesia discovered simultaneously by Cathelin and Sicard. When applied merely to relieve the pain of neuralgia, the method does not differ radically from perineural injections in the continuity of nerves. The author's paper is essentially a comparison of the two methods. The older of the latter is somewhat more readily carried out, but this drawback is more than offset by several points of disadvantage. The epidural injections, for example, affect a wider nerve distribution, and are less provocative of present and after pains. Blum has used the epidural method in over a thousand cases with a much smaller incidence of unpleasant consequences and sequelæ than has been shown by perineural injections. Paralysis of the peroneus has been noted occasionally under both methods. Nevertheless the conclusion of the author that the epidural method is the best routine procedure seems to be doubtfully asserted.

The Meiostagmin Reaction in the Differentiation of Tuberculosis According to Animal Species.—Gasharrini endeavors to show that this reaction is capable of the differentiation of human, bovine, and fowl tuberculosis from one another. The communication is very brief and based principally on experimental tuberculosis produced in guinea-pigs and rabbits by the various bacilli supposedly peculiar to each species of animal indicated. By following the usual technique a positive, specific reaction was obtained in four or five days after infection. The meiostagmin reaction has been used very largely of late in connection with the diagnosis of specific diseases; but this claim in connection with specific animal tuberculosis, seems stronger than any heretofore made.

Cryptogenetic Tetanus.—Stromeyer under this term refers naturally to the ancient tetanus rheumaticus, or tetanus not the result of a wound. It was thought that the discovery of the bacillus in 1884 had done away with this doubtful clinical affection; but the returns since have shown that the frequency of these paradoxal cases is in no wise diminished. It has naturally been asserted that the causal element in the two conditions differs radically; in other words, the cause of cryptogenetic tetanus is quite different from that of traumatic tetanus, just as the two clinical conditions are quite dissimilar. The possible chance of confusion in such cases is extraordinary. Thus a patient may behave clinically as a tetanus patient and yet recover. On the other hand, a patient ill of any affection whatever, may die under tetanic symptoms. The upshot of the paper is that trismus is a symptom, which may arise under various circumstances and be terminal in most. No other explanation seems possible among so many and varied symptoms.

Deutsche medizinische Wochenschrift, August 11, 1910.

Treatment of Phobias.—Cramer introduces certain more or less novel concepts under the head of symptoms and treatment of phobias. The German word "Angst," which is usually anglicized "phobia," means much more than the latter; it is employed, for example, in connection with subjective choking sensations, and similar sensations of undoubted organic origin; while we usually restrict the term phobia to subjective experiences which are not based on organ sensations. Cramer would use the expression "psychopathic fear" as an equivalent of what we term "phobia." He seems inclined to believe that the association of phobias with digestive disturbances is accidental. People with the same antecedents may be predisposed to both conditions alike. This seems a not unreasonable explanation of the frequent association of gastric insufficience with psychic insufficience. The prompt relief of both trains of symptoms after a brief change of surroundings is a sufficient document to show that both conditions depend wholly on a common cause. Much more significant is the relationship of the sexual life to phobias. But all that can be said is that the sexual element is operative chiefly in predisposed subjects. The most novel and unconventional position of the author is asserted in connection with the opium treatment of psychopathic phobias. From our native standpoint such a management, especially outside of institutions, would be self-condemnatory. The author appears to recommend it for pathological fear of all kinds. The dose of opium should be small at the outset, and gradually increased. It does, indeed, seem strange that a properly constituted authority should prescribe a graduated opium cure for any disease whatever, even if incurable. Yet there is no doubt that Cramer orders a full opium treatment for phobias, as if it were a specific. The nearest approach to such a course is in Flechsig's opium-bromide treatment of epilepsy; but in the latter the remedies are more or less alternated.

Sudden Blanching of the Hair.—Stieda revives the old more than suspicion that whitening of dark hair over night is in reality a sort of withdrawal symptom, due to sudden deprivation of the walnut stain or whatever dyestuff is in daily recourse; whence the frequency of alleged cases after incarceration. It is no longer believed by experts that psychic trauma has ever caused this transformation. Mental shock is extremely common; while blanching of the hair at a stroke is so rare that a list of alleged cases may quickly be compiled. It is true that psychic trauma may appear to cause blanching of the hair within a comparatively short time—a few weeks, perhaps—but the author deals only with alleged instantaneous cases. There is absolutely no evidence that such a sudden depigmentation has ever occurred or could possibly occur.

The Ehrlich-Hata Remedy in Complicated Syphilis.—Wechselmann, after the usual laudatory contribution to the virtues of "606," touches mildly on untoward effects of the remedy. A train of symptoms which might have erroneously been ascribed to arsenicism is explained by the supposition that the remedy may activate latent bacterial infection. Thus, if we suppose that a patient at the time of the injection chanced to suffer from a bacteriogenic angina or otitis media, the said injection might cause the complication to pursue a more active course. A number of complicating conditions of the most diverse kinds, but all such as are sometimes influenced by arsenical medication, remained unaltered. It is implied that at least one case of abortion has been ascribed to the drug.

Book Reviews.

Light Therapeutics. A Practical Manual of Phototherapy for the Student and Practitioner, with Special Reference to the Incandescent Electric-Light Bath. By J. H. Kellogg, M.D., author of "Rational Hydrotherapy," "The Art of Massage," etc. Member of the British Gynecological Society, the International Periodic Congress of Gynecology and Obstetrics, American and British Associations for the Advancement of Science, the Société d'Hygiene of France, American Society of Microscopists, American Climatological Society, American Medical Association, Michigan State Medical Society; Superintendent of the Battle Creek (Mich.) Sanatorium. Battle Creek: The Good Health Publishing Co., 1910.

This little book of 200 pages is an exposition of the light therapeutics as used at Battle Creek. Beginning with a discussion of the physics of light and the physiologic effects of it upon tissues, it then goes on to the therapeutic effects of light, both natural and artificial, upon the human body in disease. The arc light is discussed, but especial attention is paid to the incandescent light treatment by means of cabinets, though the photophor is also described. The various therapeutic measures of hydrotherapy, massage, friction, and air blasts which may be used in association with phototherapy are described. Under clinical phototherapy are taken up the various diseases which the author believes may be benefited by his methods of treatment, ranging from scarlet fever to diabetes and fractures. The book is well printed and profusely illustrated, and reviews concisely and completely the measures in general use in the modern sanatorium, going into sufficient detail to enable the reader to carry out the treatments by himself provided that he is the owner of the necessary paraphernalia.

Duodenal Ulcer. By B. G. A. Moynihan, M.S. (Lond.), F.R.C.S. (Leeds). Illustrated. Philadelphia and London: W. B. Saunders Co., 1910.

It is always a pleasure to review a book on a special subject written by a master, and the reader of this cannot help being infected by some of the enthusiasm of its author. In the chapter on history we learn that neither Curling (after whom the lesion is often called) nor Dupuytren were the first to call attention to the connection between burns and acute ulceration of the duodenum, but Long of Liverpool, in 1840. Moynihan attacks without mercy some of our most cherished ideas. "Acid dyspepsia," "hyperchlorhydria," "gastric neuroses" are ruthlessly tossed away. He says there is "no foundation in fact for this venerable fallacy," *i.e.* excessive acidity. He makes his diagnosis almost exclusively on the history-pain and discomfort in the epigastrium following about two hours after meals. The only physical signs to be looked for are tenderness in the midline of the upper part of abdomen and to the right, firm contraction and rigidity of the right rectus muscle, and a briskness of the right epigastric reflex. These are all of relatively small importance. Hematemesis and melena are complications whose occurrence should have been forestalled. The author affirms that in his experience the diagnosis of duodenal ulcer is made with a degree of accuracy not exceeded in the case of any other abdominal disorder. The treatment of chronic duodenal ulcer, he says, should be invariably surgical. His description of perforation is beautiful, and reads like a story. An appendix to the book contains a detailed statement of the cases operated on during nine years.

Scientific Living for Prolonging the Term of Human Life. The New Domestic Science, Cooking to Simplify Living and Retain the Life Elements in Food. By Laura Nettleton Brown. New York: The Health-Culture Co., 1910.

This book is written by one who would apparently like to join the ranks of the raw-food faddists, but still is a little too sensible to endure altogether that folly, with its unpalatable and unhygienic excesses. She therefore refrains from urging the exclusive use of uncooked foods, but comes pretty near it. However, some of the dishes she recommends, and for which she gives recipes, are not bad, and the author has done a service to her kind in giving little gastronomic comfort to the raw-fooders. She gets a little afield at times when she leaves the menus and begins to philosophize. For instance, in speaking of tea, coffee, wine, and tobacco, she especially remarks: "The purpose of such poisons in nature is to discipline the mind. Man has the privilege of deciding between things, thoughts, and actions that sustain life and those that induce death. He is strong physically, mentally, and morally in proportion to his decision to maintain life." The book isn't really so bad, for this is about the worst thing we have found in it, unless perhaps it is the author's diatribe against salt. Of the yeast germ, she says it is more plant than animal.

Studies from the Rockefeller Institute for Medical Research. Reprints. Volume X, 1910.

The publication of this volume marks the completion of the tenth year of existence of the Rockefeller Institute and the sixth year of its control of a laboratory of its own. To the usual collection of reprints of investigations is prefixed a complete list of the staff and extramural workers of the institution since its organization. An index of the first ten volumes is also added. The body of the report itself consists of fifty-five articles, comprising the work of the Rockefeller Institute published during the year 1909. The subjects cover practically all departments of scientific medical research, and are far too diversified to make a thorough review possible. Possibly the portion of the book of the greatest interest to the practitioner is that consisting of five articles by Flexner and Lewis upon poliomyelitis. A glance at the index for the first ten years of the reports impresses one most forcibly with the tremendous scope of the work which has been carried on under the auspices of the Rockefeller Institute and the immense amount which has been accomplished during the first decade of its existence.

The Diagnosis of Smallpox. By T. F. Ricketts, M.D., B.Sc. (Lond.), M.R.C.P., D.P.H.; Medical Superintendent of the Smallpox Hospitals and of the River Ambulance Service of the Metropolitan Asylums Board. Illustrated from photographs by J. B. Byles, M.B., B.C. (Cantab), F.R.C.S. (Eng.), D.P.H.; Senior Assistant Medical Officer at the Smallpox Hospitals of the Metropolitan Asylums Board. With 12 colored plates, 110 black-and-white plates, and 14 charts. New York: Funk & Wagnalls Co., 1910.

This book is of especial interest on account of the large collection of really superb photographs which are used as illustrations and of the theory which the author propounds and most ably discusses that in many cases the distribution of the rash in variola is due to the stimulation of external irritations, as the pressure of the hat band, belt, garter, the irritation of plasters, and many other causes. The text is clear, well written, and to the point. The various forms of smallpox are described, and especial attention is paid to differential diagnosis, some of the best illustrations being of cases not of variola, but of other conditions easily mistaken for it. The book confines itself to diagnosis, which is by far the most important feature in such a disease as smallpox. It is by far the best work upon the subject which has appeared recently, and should be owned by every man whose work brings him into contact with cases of variola. The volume is well printed, in large, clear type, superbly illustrated, and neatly bound.

The Excursions of a Book-Lover, Being Papers on Literary Themes. By Frederic Rowland Marvin. Boston: Sherman, French & Company, 1910.

This delightful volume is enriched by the many-sided personality and attainments of its author. Dr. Marvin is not only a writer of great charm and finish, but a Doctor of Divinity and a Doctor of Medicine, and therefore his point of view, not only of books, but of life and people also, is enhanced by the deep insight of a nature that has touched life at many points. In his book we find nothing of the cool monastic retreat from actualities too often characteristic of the book-lover who loves only books. And how he loves them! Outside and in, his "dearly beloved old pigskin tomes." As he says in his admirable foreword, "the gladness of many evenings is in these pages." The reader may take up this volume with an assurance that the promise of interest contained in the titles to the essays will not fail of fulfilment—"Literary Fame," "Book Dedications," "Shakespeare's Bones," "Holographs," "At Last the Silent Majority," each one both piquing interest and rewarding it. Of special interest to physicians is the essay entitled "The physician and his work," where is to be found quoted in full the statement of the physician who attended Washington in his last illness, which was published in the *Medical Repository* in 1800, about one year after his death, and in juxtaposition to this the comment upon it published in the Medical Record in 1900, just one hundred years later, which runs in part as follows: "The treatment of an old man, sick with a disease very exhausing to vitality, and so severe that the illness lasted but twenty-four hours, consisted in the abstraction of between two and three quarts of blood, the administration of about gr. xx of calomel and gr. vi of tartar emetic, an injection, with application of a blister. * * * The almshouse patient to-day has more rational treatment than the ex-president of the United States had in 1800."

Society Reports.

THE AMERICAN GASTROENTEROLOGICAL ASSOCIATION.

Thirteenth Annual Meeting, Held at St. Louis, Mo., June 6 and 7, 1910.

First Day—Monday, June 6.

THE PRESIDENT, DR. JULIUS FRIEDENWALD OF BALTIMORE, IN THE CHAIR.

Recent Events in the Development of Gastroenterology.—Dr. FRIEDENWALD delivered this, the presidential address (see page 270).

Stretching of the Cardia in the Treatment of Cardiospasm and Idiopathic Dilatation of the Esophagus.—By Dr. MAX EINHORN of New York. This was a detailed report of two cases of cardiospasm and three of idiopathic dilatation of the esophagus successfully treated by repeated stretching of the cardia by means of a metallic cardiodilator constructed by the author. The success of this treatment in these cases had induced him to try a similar method of treatment in pylorospasm, and in some cases of that condition he had apparently had good results by stretching the pylorus.

Duodenal Alimentation.—By Dr. MAX EINHORN. (See page 92.)

Cardiospasm, with Dilatation of the Esophagus.—Dr. JESSE S. MYER of St. Louis read this paper, in which he reported ten cases of cardiospasm, seven males and three females, treated by forcible dilatation from above. He emphasized the importance of early diagnosis and early relief of the spasm in order to restrict as much as possible the sac development. It was questionable, he thought, that a sacculated esophagus ever fully regained its normal tone; long after the spasm had been completely relieved, certain symptoms persisted because of this fact. Dr. Myer said that his experience with this series of ten cases led him to the belief that there was a congenital basis for the development of the sacculation. These individuals presented certain well-defined outward evidences which indicated a congenital tendency to a general asthenic state. That cardiospasm was of nervous origin seemed to be the general consensus of opinion. How or why it developed in certain persons, however, had never been satisfactorily explained. Many etiological factors had been considered in the previous case reports, but in none, perhaps, with the possible exception of trauma, had any essential connection been determined. For the development of cardiospasm, as for certain other conditions dependent upon nervous causes, there were probably necessary two factors, *i.e.*, a predisposition and an irritant. The dilator which Dr. Myer used in the stretching of the cardia in his cases consisted of a double rubber bag, with a silk bag inserted between them, and attached to the ordinary stomach tube having no opening in the end.

Tortuous Stricture Involving Three and a Half Inches of the Cardiac End of the Stomach Treated by Gradual Dilatation.—Dr. BERTRAM N. SIPPY of Chicago reported this case and gave a demonstration of the instrument he employed.

Dr. CHARLES G. STOCKTON of Buffalo said he had had some experience with cardiospasm and with its treatment by dilatation, and while he had succeeded in some instances, there were others in which the result was not satisfactory. He had had cases where he did not succeed in passing a dilator.

Dr. ALLEN ARTHUR JONES of Buffalo said the condition of cardiospasm was one of the most difficult that internists and gastroenterologists had been called upon to treat. Surgical interference in these cases was not altogether satisfactory. The only operation that had been feasible in most instances had not attacked the disease at all, but had simply been undertaken to short-circuit it and feed the patient through an artificial opening. For this operation, it might be said in its favor that some cases of cardiospasm were greatly improved by it, and it was possible in a few instances to allow the artificial opening to close, and thereafter the patient was able to take his or her food in the normal manner. In those cases, one could not help feeling that the condition was accompanied by some intermittent or continuous irritation, either direct or indirect, which gave rise to the spasm and closed the esophagus and cardia, and that the operation allayed the irritation and overcame the spasm.

Dr. JOHN A. LICHTY of Pittsburg believed we were coming more and more to feel that gastric ulcer was not a local disease; that it was rather a disease due to constitutional, nutritional disturbance, and if we must feed these patients by the rectal method or starve them, we were to that extent hazarding their chances of recovery by further interfering with their nutrition. Therefore, if this method of Dr. Einhorn's of feeding the patient directly into the duodenum by passing a tube through the pylorus proved successful, we had made a great step in advance in the treatment of gastric and duodenal ulcer.

Dr. A. L. BENEDICT of Buffalo said he had never seen a case of esophageal spasm which required any extreme treatment. One or two passages with an ordinary bougie, a little valerian, perhaps suggestion; at any rate, very mild measures were sufficient to relieve the condition. In his own experience, we had a very simple type of esophageal spasm which yielded readily to mild measures of treatment, or else we had to deal with a distinctly organic or at least mechanical obstruction.

Dr. EINHORN said that in his paper he had differentiated between cardiospasm and idiopathic dilatation of the esophagus. Cardiospasm was a frequent condition and was easily cured in many instances. It was a neurotic affair. With idiopathic dilatation of the esophagus, however, no matter how originally produced, we found a different picture. These patients were never cured with drugs or suggestive measures, and even the introduction of small-sized bougies would not cure them. When, however, we began to dilate forcibly, over-stretching the cardia and making it much larger than normal, then we might accomplish a cure. Cardiospasm and idiopathic dilatation of the esophagus were two entirely different conditions, and we should not mix them up.

Dr. JESSE S. MYER said he was not yet quite clear as to how Dr. Einhorn differentiated clinically between cardiospasm, with dilatation of the esophagus, and idiopathic dilatation of the esophagus. Dr. Myer said his own cases were all examples of cardiospasm with dilatation. If the cardiospasm were primary, then we were perfectly entitled to consider the condition as cardiospasm, with dilatation of the esophagus. Under those circumstances, however, we were not justified in calling it an idiopathic dilatation.

Thyroidism as a Causative Factor of Gastric Disturbances.—Dr. MAX BALLIN of Detroit read a paper on this subject, in which he offered the following conclusions: Thyroidism is a complex of symptoms caused by faulty secretion of the thyroid gland. Besides the principal symptoms (heart, nervous and eye symptoms and goiter), intestinal symptoms (diarrhea, vomiting, etc.) and disturbances of metabolism (loss in weight) were very important; more so, as the latter might occur early in the course of the disease and might be more pronounced than the former. Therefore, the diagnosis in those cases where the intestinal symptoms predominated might be difficult, and should be based upon accurate examination as to the existence of slight degrees of goiter, tachycardia and slight eye symptoms. As to treatment, surgical inter-

ference, if serum and medical treatment failed, would nearly always cure the intestinal symptoms; in fact, often earlier than the cardiac and eye symptoms. A suitable operation (ligation of the thyroid arteries, resection of the gland or enucleation of tumor from the gland) would be followed most frequently by a surprising gain in weight, and would check the acceleration of metabolism with its tissue waste.

Dr. JOHN P. SAWYER of Cleveland said that in view of the enormous frequency of thyroidism in the district in which he lived and in other localities, he did not feel that it was warranted that operative interference should be too frequently recommended. He had seen instances where large goiters pressed on the trachea and gave rise to pronounced symptoms of obstruction; yet they receded and were symptomatically cured under medical treatment. On the other hand, he could recall a number of instances that were operated on with only temporary relief. He was convinced that the best method of treatment in these cases was not yet generally known, but in most instances he would have grave doubts about recommending thyroidectomy.

Dr. J. H. STEALY of Freeport, Ill., said he had been on the lookout for cases of enlarged thyroid or hyperthyroidism for over twenty years, and up to ten years ago, in his section of the country, not five per cent. of these cases were ever diagnosed. Now about 60 per cent. were recognized. As to the operative treatment of these cases, he was in favor of removing the entire thyroid, with the exception of a small portion, say the size of a penny. He had removed the entire gland in a large number of cases, and up to the present time no symptoms of hypothyroidism had developed by leaving the parathyroids.

Dr. BALLIN, in closing, said we should save as much of the thyroid tissue as possible. Nobody to-day was in favor of complete thyroidectomy, which would lead to myxoedema. We should only tie as many arteries or remove as much of the gland as was necessary to overcome the symptoms.

Achlorhydria Hæmorrhagica Gastrica as a Symptom of Chronic Gastritis.—Dr. JAMES TAFT PILCHER of Brooklyn, N. Y., read this paper, which gave the result of his investigations made in the pathological laboratories at St. Mary's Hospital, in Rochester, Minn. He stated that there was a definite entity presented in the stomachs of some patients suffering from various intra- and extra-abdominal pathologic conditions, which was characterized by the absence of hydrochloric acid and the presence of "occult" blood. The condition was probably primarily affected through the agency of a reflex nerve stimulation, inhibiting first the production of free hydrochloric acid to only a moderate degree. This so modified the inhibiting factor of the gastric juice that the necessary conditions for the growth of pathogenic bacteria were furnished, chief among which were to be reckoned the streptococci and colon group, which were present in striking numbers. These direct irritations either themselves or in conjunction with the primary irritative factor, gallstones, appendicitis, pancreatitis, etc., perpetuated the pathological process until there was an achlorhydria produced. It was most probable that to the erosion following this irritation the presence of blood might be ascribed. In the one hundred stomachs examined at operation, atrophy was never present, nor was there, excepting in one case, any evident insufficiency of the pylorus. There was a general symptomatology accompanying this condition which was very suggestive. The test meal recovered was indicative of the pathological process in the stomach. There were indications in but seven cases observed that there was no secretion from the stomach mucosa. In others, the presence of mucus, the biuret reaction, and coagulation after activation would tend to show that there was still a moderate degree of enzymic action. The cases were therefore not "achylia gastrica." Many instances were shown which illustrated the progressive, established or retrogressive stages of this condition. Proof of the etiological factors had been demonstrated in the cases operated upon, deduced from their prompt and permanent recovery. The condition was relatively common, approximately one in every fifteen stomach cases examined.

Dr. MAX EINHORN of New York said that some years ago (MEDICAL RECORD, June 23, 1894) he published his first article on Clinical Observations on Erosions of the Stomach and Their Treatment, and five years later (*Journal of the American Medical Association*, May 20, 1899) his second article on Further Remarks on Erosions of the Stomach appeared. In those articles he reported a series of cases in which the presence of particles of gastric mucous membrane appeared in the stomach washings, and these, under the microscope, were found to contain glandular elements. In these cases, the absence of hydrochloric acid was also noted in some instances; in some there was complete achylia and in others hyperchlorhydria. In all of them there were various subjective symptoms of gastric origin, which, together with the small pieces of gastric mucosa, clearly indicated the presence of gastric erosions. The condition was found associated with catarrhal gastritis, sometimes of the alcoholic type. He never had a chance to get an autopsy on any of these cases, because all of his patients recovered under treatment, but he did not doubt that a similar condition existed in association with other troubles.

Dr. JOHN A. LICHTY of Pittsburg said the one point which interested him particularly in Dr. Pilcher's paper was the relatively large number of cases of achlorhydria or hypochlorhydria, and the few cases of achylia gastrica, and it seemed to him to be within the range of possibility that in the cases he examined the patients were under abnormal conditions, and did not secrete their normal gastric juice. Probably, in many of them, serious operations were contemplated; they were in a more or less perturbed state of mind, and this might have disturbed the normal gastric secretions.

Dr. JOHN P. SAWYER of Cleveland said it was well to keep in mind the fact that repeated examinations, at considerable intervals of time, were necessary in order to determine that given findings were essential or particularly peculiar to the pathological condition determined clinically, or perhaps afterward recognized as post-mortem.

Dr. A. L. BENEDICT of Buffalo referred to the unreliability of the blood tests that were employed for occult blood. There were quite a number of different substances that would oxidize guaiac and other things, and some authors gave such a large list, including the ferments, starch, mucus, and other substances liable always to be present, that it seemed we must check off our tests for occult blood before we could draw any reliable conclusions therefrom.

Dr. PILCHER, in closing, replying to Dr. Einhorn, said that in all the stomach washings he had made in these cases he had never been able to identify any cellular elements that could be referred to the stomach mucosa. He had never seen any clumps of cells or any cells which would in the least give one any idea of the condition of the gastric mucosa. As to the suggestion made by Dr. Lichty that the loss of acidity was possibly temporary and associated with a nervous condition of the patient, Dr. Pilcher said he did not think this was so. This so-called "nervous achylia" was very simply differentiated, and the experienced observer could in most cases tell immediately whether he was dealing with a real achylic stomach or a "nervous achylic" stomach if he would merely make a smear from his residue and stain it with any ordinary stain, and find out what the bacterial content was. In the normal stomach there were very few bacteria, and if we

were dealing with a case of nervous subacidity or complete acid due to the same cause, we would not find the enormous number of bacteria that were present in true achylia, nor would we find the pathogenic varieties which were so universally present under diseased conditions.

Observations of the Variability of the Composition of the Gastric Juice.—Dr. E. L. Eggleston of Battle Creek said that repeated test meals given the same individual under as nearly the same conditions as possible indicated a considerable variation in the acid and pepsin secretion, the secretion being no doubt influenced by psychic conditions. What might be termed the normal secretion in any individual fluctuated to a considerable degree, being influenced both by the mental condition and the kind of food taken. The state of mind—the mental condition—of the patient at the time of the test meal was decidedly unfavorable to normal digestion. As the ordinary test meal was not inviting, this also failed to arouse what Pawlow termed the "appetite juice," and the secretion obtained at the end of an hour might be very misleading. When possible, a specimen of the gastric ontents should be taken after the patient had eaten of food that was appetizing and under pleasant conditions. Aside from the psychic influences which ased a variation in the composition of the gastric secretion, it was possible to greatly influence it by the kinds of food taken. It was possible in this way to greatly increase the secretion, or to reduce it almost to *nil*. The author summarized his paper as follows: 1. That with the same food materials there may be quite a marked variation in the percentage compostion of the gastric juice, which will result from psychic influences. 2. Iced foods or beverages have only a slight inhibitory action on the gastric secretions. 3. Foods containing free fats in any quantity, when taken either at ordinary temperature or frozen, have a decided inhibitory effect on the gastric secretions. 4. Fruit juices, either frozen or at ordinary temperature, quite markedly increased the secretion. 5. Tincture of gentian compound seemed to have but little effect as a gastric stimulant.

Dr. J. C. Johnson of Atlanta said that when we considered the personal equation and variations in the vital equilibrium, he did not doubt for a moment that we could find a considerable variation in the acid and pepsin secretion, even in the absence of any evidence of ill health, but in order to determine the exact physiological value of such findings, they must be shown to be on an entirely physiological basis, and, at the same time, such findings must be more or less uniform.

The discussion was continued by Dr. Gustav Baar of Portland, Ore., and was then closed by Eggleston.

Some Experiences with the Einhorn Duodenal Bucket.—Dr. W. G. Morgan of Washington, D. C., in this paper reported in detail 19 cases in which he had used the Einhorn duodenal bucket for the diagnosis and localization of ulcers of the stomach and duodenum. He used both the thread test and the duodenal aspirator, and from his experience with these two methods he realized that Dr. Einhorn had given us means to employ which rendered the diagnosis in these cases comparatively easy and reliable. The application of the thread test was readily applicable to most cases, there being only here and there an individual who objected to the procedure. We could often watch the healing of the ulcer by the lessening of the length and amount of the blood stain upon the thread. Dr. Morgan said he had modified this test by substituting a small split shot inclosed in an ordinary gelatin capsule for the bucket devised by Dr. Einhorn, and he felt that it worked even better, as the patient seemed to experience less difficulty in swallowing it; furthermore, it cost much less to have a number of such tests going on at the same time. Dr. Morgan said that the number of latent ulcers, or ulcers giving few prominent symptoms, was larger than was thought, and that by the systematic use of the thread test many cases would be found that would otherwise escape recognition. The test, although sometimes disagreeable, was not seriously objected to, and should be instituted at the faintest suspicion of ulcer. Besides being able to localize the ulcer, we were enabled to say with more certainty how the case was progressing and when the ulcer was probably cured.

Dr. Max Einhorn of New York said he had employed the thread test in over seventy cases of ulcer of the stomach, and could subscribe to its usefulness. In cancer the method could be used advantageously in recognizing and localizing the presence of a growth; it did not tell us whether the growth was malignant or benign, but it indicated the site of the ulceration. He had also found it useful in cirrhosis of the liver, with varicosities and ulceration in the region of the cardia and lesser curvature, even before the occurence of hemorrhage.

Dr. James T. Pilcher of Brooklyn said he had tried the Einhorn thread method as an aid to diagnosis in twenty-five cases of ulcer of the duodenum and in ten cases of ulcer of the stomach, as determined at operation by Dr. Mayo, and its localization of the ulcer in the cases in which he had employed it had not always been quite as definite as one might infer from listening to Dr. Morgan's paper. In the first place, in ulcerations of the duodenum, the bucket did not seem to get beyond the point of the ulceration. In four or five of his cases, however, the ulcer was definitely located by the thread and bucket method, as subsequently proven by operation.

Dr. Morgan, in closing, said that this test was still new, and that it would take many hundreds of cases to properly estimate its value, but from his experience he believed it would prove to be one of the most valuable guides in the recognition of peptic ulcer.

Hyperacidity and Abdominal and Pelvic Surgery.—Dr. J. H. Carstens of Detroit read this paper (see page 318).

Dr. Allen A. Jones of Buffalo said that in considering this question we should be very careful in deciding what we meant by hyperacidity, and that it was an error to allow the patient to make the diagnosis for us. Many patients complained of extreme gastric acidity when they were not suffering from that condition at all. If we had a definite reason for feeling that the cause of the excessive acidity rested in some other organ than the stomach, such as the gallbladder or appendix, an operation was certainly indicated, but he protested against opening the abdomen with the idea, as Dr. McPhedran of Toronto had put it, of going on a roving expedition.

Dr. Gustav Baar of Portland, Ore., said he had found that excessive indican in the urine was frequently associated with hyperacidity, and when indicanuria was a constant symptom, he became convinced that it was an indication of the presence of an actual intra-abdominal lesion of the appendix or elsewhere.

Dr. J. C. Johnson of Atlanta said we either had to regard an excess of hydrochloric acid as an entity, or not regard it as such; it was either a disease or a symptom of a disease. In either case, the causes producing this pathological condition must operate in essentially the same way, and whatever the remedy might be, whether the knife, or alkalies or diet, the essential cause must be removed by the employment of the same factors whose perversion led to its development.

A Clinical Study of 600 Cases of Colitis.—By Dr. George D. Kahlo of French Lick, Ind. This paper embraced a résumé of 625 cases of chronic colitis, including both the inflammatory and secretory forms, the subject being treated entirely from the clinical standpoint. Statistics were given showing the sex, age, duration of the disease, and the relative frequency of prominent symptoms,

as also the occurrence of the more common complications. Errors in diagnosis often led to unnecessary surgical interference. The author believed that treatment should be directed to the local condition, as well as to the neurotic influences that had acted to produce the disturbed secretory function. In prescribing a diet, consideration should be given to disturbances of the digestive function and to the state of nutrition. The effect of mineral waters of the alkaline-saline group, both internally and locally, was also referred to, as were the influences of psychotherapy, massage, and hydrotherapy.

Dr. John A. Lichty of Pittsburg, discussing the treatment of these cases, said he was a great advocate of the warm oil enema, but more than that, he believed that the cure lay in the correction of the disturbance of nutrition, such as we often found associated with splanchnoptosis. If you fattened your patient and increased the amount of fat in the abdominal cavity, the mucous colitis would often disappear without any other treatment.

Second Day—Tuesday, June 7.

On the Adaptation of the Human Saliva to Diet.—Dr. Lafayette B. Mendel of New Haven read this paper (See page 340).

Further Observations on Alcoholic Gastritis and Its Relation to Experimental Gastritis in Animals.—By Dr. Nellis B. Foster of New York (see page 275).

Dr. Julius Friedenwald of Baltimore said that about five years ago he published a paper on the pathological effects of alcohol on rabbits, the work being done in the Pathological Laboratory of the Johns Hopkins University and Hospital, and the results of his work correspond very closely to those reported by Dr. Foster. The quality of alcohol taken by the rabbits varied very much according to the size and strength of the animal; certain rabbits were found to be so resistant that they seemed capable of tolerating daily intoxicating doses for an indefinite period.

Dr. G. H. Benton of Chester, W. Va., said that Dr. Foster spoke of stimulation in reference to the effect of alcohol on the gastric mucosa. The speaker thought this should be regarded as an irritation rather than stimulation. This particular application of alcohol produced an excretion of a thick, tenacious mucus, which was Nature's way of protecting the mucous membrane of the stomach.

The discussion was continued by Drs. Lichty, Johnson, Benedict, Charles D. Aaron of Detroit, and Nathan Rosewater of Cleveland.

Anthropometric Studies of the Osseous Proportions of the Human Body: With a View to Obtaining a Mathematical Expression for Enteroptosis.—Dr. John C. Hemmeter of Baltimore said that enteroptosis was not an abnormality limited exclusively to displacements of the abdominal viscera, but that the thoracic organs were also displaced as far as the diaphragm and the osseous limitations of the thorax would permit it. By radiographic and other methods of investigation the author had become convinced that enteroptosis was an expression of a general osseous, visceral, nervous, and vasomotor abnormality. Acquired enteroptosis was comparatively rare, and then only showed displacements in a few organs of the abdomen. In the acquired form, the thoracic organs, as a rule, were in normal position, and the osseous anthropometric proportions of the body were not found to be deviated from the normal, while in the inherited and more frequent type the thoracic organs were rarely in normal position; there were always several abdominal organs out of position, and the osseous proportions were decidedly abnormal.

Dr. Johnson said he was struck by the frequency with which Dr. Hemmeter had observed displacements of the thoracic organs. In his own observations, which were confined more especially to the abdominal organs, he had never yet failed to recognize some displacement or rather lack of proportion between the thoracic and abdominal organs in patients with enteroptosis or gastroptosis.

Dr. Gustav Baar said he was convinced that most cases of enteroptosis were acquired. The condition was rarely observed in children, at least in his experience, and he believed that the chief causative factor was the pressure of the corset in women or the trousers' strap in men. He believed that very few of these cases were congenital, and that ptosis of the thoracic organs was very rare compared with ptosis of the abdominal organs.

The discussion was continued by Drs. Friedenwald and Pilcher.

Chylous Cyst of Mesentery.—Dr. A. L. Benedict of Buffalo presented a report on a case of chylous cyst of the mesentery in a boy of six years, who was operated on by Dr. Charles E. Congdon. So far as the writer could ascertain, no other case had ever been recognized in Buffalo, although chylous ascites and chylothorax had. The largest series of cases in the literature amounted to twenty-five. Dr. Benedict had, thus far, collected about sixty-five cases, and had found three cases prior to Rokitansky's in 1848, which had previously been supposed to be the first authentic one. Two indubitable cases were found in the reports of the Paris Academy in 1710 and 1727. It had been declared that sugar was an essential constituent of genuine chylous effusions, Senator being quoted as authority. Dr. Benedict's case yielded no sugar, and he showed that Senator had been misquoted as considering sugar as anything more than a usual constituent; that sugar had been absent in other cases, and that, on purely physiologic grounds, it could not be considered an essential ingredient. A study of the etiology showed that obstruction of the receptaculum and thoracic duct was rarely a cause, and that, indeed, such obstruction would tend to immediate chylous ascites or chylo-thorax; also that the theory of embryonal rests was not supported by conclusive histologic evidence. From experimental results it seemed possible that any rise of abdominal pressure might operate, if not to produce the original cavity, at least to cause the development of a macroscopic cyst. Hence, the rather characteristic history of colicky pains might have both a diagnostic and an etiologic bearing, though the frequency of such pains in their association with cyst was too slight to let such a history influence us, excepting in a suggestive way. The physical diagnosis of abdominal cysts, by auscultatory percussion, tuning fork percussion, transillumination, etc., and the exclusion of certain common types of abdominal tumor were discussed. Without claiming that a positive diagnosis could be made, Dr. Benedict thought that in favorable cases operation could be undertaken with the fairly positive diagnosis of some sort of cyst, with the probable diagnosis of mesenteric cyst, and with at least the knowledge that there was such a thing as chylous cyst of the mesentery.

Dr. George W. McCaskey of Fort Wayne referred to a case which he saw about twenty years ago in which he made a diagnosis of pericardial effusion. This seemed justified by the muffled heart sounds and by the outline of the cardiac dullness given by percussion. A paracentesis was done, and chylous fluid was obtained. He believed the cases was one of chylous pericardial effusion.

Dr. C. F. Korssell of Chicago reported in detail a case of chylous ascites in combination with multiple, small chylous cysts. The largest cyst formation was found between the layers of the peritoneum in the transverse mesocolon, holding over one quart of oily chyle.

Dr. Benedict, in closing, said that in a recent review of the subject, he found a record of two cases of chylous cysts of the pericardium.

The Clinical Features of Metastases Involving the Nervous System Secondary to Cancer of the Stomach.—Dr. Henry L. Elsner of Syracuse said that metastases

due to malignant disease of the stomach and intestines as they involved the nervous system were exceedingly rare; not so rare, however, as had been supposed in the past. Thorough search would frequently uncover clinical manifestations which made their presence positive. These conclusions were confirmed by post-mortem findings. In occasional cases, metastases of the spine, brain, and periphery caused such intense suffering and their symptoms were so prominent as to mask partially or entirely the primary growth in the stomach or intestines. Cancers of the stomach might be so localized as to give rise to a few symptoms, while metastases springing from such growths might invade the nervous system, particularly the spine, and lead to a definite train of symptoms. Cancer of the stomach, more particularly, might remain latent during a number of years, during which time metastases followed which might occasionally invade the nervous system. It was important to differentiate the various manifestations associated with pernicious anemia, included under the "Lichtheim symptoms," and those due to invasion of the central nervous system, particularly the spine, secondary to cancer of the stomach or intestines.

The Relation of Gall-Bladder and Duct Diseases to Gastric Function, Based Upon Clinical and Experimental Observations.—Dr. J. A. Lichty of Pittsburg read a paper on this subject, in which he offered the following conclusions: 1. A lesion of the gallbladder and ducts may disturb gastric function. 2. This disturbance may consist of a hypersecretion of gastric juice, especially of the hydrochloric acid, and a diminution of gastric motility, and was in direct proportion to the extent of the pathology present. 3. So-called hyperchlorhydria should be looked upon as a symptom of some organic condition somewhere along the gastrointestinal tract, and should be treated symptomatically only when organic disease could be excluded with a satisfactory degree of certainty. In the experimental work referred to by Dr. Lichty, it was attempted to show in dogs whose normal gastric secretion had been determined that by placing infected foreign bodies into the gallbladder, a condition similar to cholelithiasis in the human being occurred, and a change in the gastric secretion and motility took place, much as was found clinically.

Dr. Allen J. Jones said that in not a few instances he had found that definite disturbances of secretion—not necessarily hyperchlorhydria—or of motion were associated with gallbladder disease. Furthermore, he agreed with Dr. Lichty that extensive or quite marked morbid conditions of the gallbladder, especially pericholecystitis with adhesions, were not infrequently associated with gastric disturbance. On the other hand, there were cases in which the cause of the gastric symptoms lay in the stomach itself rather than in a morbid condition of some of the other abdominal organs. We should also bear in mind that two or more morbid conditions may exist in the abdomen: the patient may have appendicitis or cholecystitis, and may also have an abnormal condition of the pylorus.

Dr. Fenton B. Turck of Chicago said he had no doubt that the infection of the gallbladder in dogs produced by placing an infected foreign body into that organ, influenced the secretion and motility of the stomach, but whether there were other factors associated with this had not been touched upon in this research by Dr. Lichty.

Dr. J. C. Johnson said that in dealing with cases of gallstones and gallbladder adhesions, we all knew that these conditions produced a certain train of symptoms, but what we wanted to learn was, how did they do it and why did they do it? Before gallbladder trouble, appendicitis or anything else could produce hyperchlorhydria, there must be a disturbance in metabolism of the secretory cells of the stomach.

Dr C. F. P. Korssell of Chicago said he had almost invariably found that patients with enteroptosis also suffered from hyperchlorhydria and indicanuria. By keeping this fact in mind, he had relieved many patients who were not benefited by having their appendix removed, or their Fallopian tubes amputated, or their uterus curetted, etc.

Dr. James T. Pilcher of Brooklyn called attention to the fact that we might have these gastric disturbances due to impaired metabolism of the nerve structures. That was really an organic ondition, not merely a functional one. We might have an actual change in the nerve, and in that case it could not be regarded as a functional hyperchlorhydria.

Dr. John P. Sawyer of Cleveland said that hyperchlorhydria seemed to be regarded by many as a continuing expression of an established disorder. Ought we, however, to regard it in that light? Hyperchlorhydria might be present for a considerable length of time in a given patient under a given set of conditions; at another time it might be absent, and the same patient may have an achlorhydria or a hypochlorhydria. We may have tremendous excursions in this respect due to psychical phenomena.

The discussion was continued by Drs. Benedict and Friedenwald, and was closed by Dr. Lichty.

Report of a Case of Inoperable Carcinoma of the Splenic Flexure of the Colon Treated with Neoformans Vaccine.—By Dr. Charles D. Aaron of Detroit. The case was one of tumor on the left side of the abdomen which upon exploratory incision proved to be inoperable. Under the use of neoformans vaccine there was an apparent disappearance of the growth and an improvement in all the symptoms.

Some Observations and Modifications on the Schmidt Test Diet.—By Dr. G. W. McCaskey of Fort Wayne. The author suggested three slight modifications in the Schmidt test diet. One was the advantage which might be gained by introducing into the diet very small cubes of raw meat which had been soaked in carmine solution for twenty-four hours. These might pass through the stomach in case the latter could not digest the connective tissue, and could be readily recognized macroscopically in the feces as small, red masses. He also advised repeating the test with one-half the quantity, approximately, perhaps, 1,200 calories, and if we still got the same results it would give us a clearer indication in regard to functional impairment. The third modification he suggested was to make it more inviting and palatable by substituting for the purées gruels, etc., properly prepared potatoes, and cereals.

The Rôle of the Bacillus Coli Communis in Disease.—Dr. Fenton B. Turck of Chicago in this paper presented some interesting facts on the rôle of the *Bacillus coli communis* in the gastrointestinal tract in producing lesions in the liver, kidney, stomach, and other organs.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held May 23, 1910.

The Vice-President, Dr. James F. McKernon, in the Chair.

The scientific session was held under the auspices of the Committee on Public Health and was devoted to a symposium on the hospital situation in New York.

Hospital Reorganization.—Dr. Charles L. Dana said that he did not come before the Society as an expert in hospital organization, but that as Chairman of the City Club he had had the opportunity of watching the work. In 1905, in an anniversary address, Dr. Gerster had presented in a very forcible way the necessity for hospital reform. In 1906 Mayor McClellan appointed a committee to make an investigation of the hospital system. The State Charities Aid Association in 1908 issued a report on hos-

pital conditions and since that time there had been a steady increase in the interest taken in the subject of hospital reform. The New York Academy of Medicine had appointed a Hospital Committee and valuable papers were presented by Dr. Goldwater and Dr. W. Gilman Thompson as a result of which the ambulance system was practically reformed, the bill only waiting the approval of the Board of Estimate. There was now a system of standardization of hospital supplies. Through a committee of the Charity Organization Society and the City Club an amendment of the city charter had been prepared providing for a system by which all hospitals would be coordinated and put on a systematic basis. This was a matter of great interest to the general practitioner, because there were about 160 hospitals in Greater New York and about 200,000 patients were treated annually. If each hospital had only three or four physicians in attendance there would be at least 1,000 practitioners directly interested in the work. There were 59 general hospitals, that was, hospitals taking in medical and surgical cases. There was each year a greater tendency on the part of the community to make use of these hospitals; people were more eager to go than formerly. In response to this greater demand the hospitals had changed their methods of administration. The medical work involved was radically different in ideals from that of a few years back. In the general hospitals there were about 10,000 beds, of which number the city supported about 3,000. The city also helped some of the tuberculosis hospitals. With the increasing and shifting population of the city it was becoming increasingly difficult to determine where to build hospitals and how large to build them. The city should take this responsibility, but as it was now organized this was impossible. The Department of Charities had nine hospitals, the Department of Health had six, and Bellevue and the Allied Hospitals had four. Each of these departments also had charge of tuberculosis hospitals and cared for tuberculosis patients. The result of this was confusion in administration. They were all doing the best that they could, but it was impossible to formulate plans for the future. There should be some single municipal power in charge. Reform would probably come in the shape of a bill amending the city charter by providing for a Hospital Department in charge of a Hospital Commissioner.

What Constitutes an Ideal Hospital.—Dr. S. S. Goldwater said that Sir Thomas More, in writing his Utopia, foresaw the needs of the New York hospitals. He stated that in the ideal community people would take more care of their sick than of others. There would be four hospitals without the city walls, each small cities in themselves. They would locate the hospitals so that contagious diseases could be isolated. They would be well stored with all things that made for the comfort and cure of the sick and the suffering would be so well attended that they would rather go there than to remain at home. Only after the best in the markets had been sent to the hospitals would the remaining people purchase their supplies. They could not to-day have a better ideal than this one given in the beginning of the sixteenth century by Sir Thomas More. Florence Nightingale's work for the hospitals had to do chiefly with sanitation. During her time conditions were such that the mortality rates were much higher in the hospitals than outside. Happily, sanitary requirements were now recognized and secured. Medical men wanted to see scientific progress, and if a hospital could show that nothing more was required of it. The hospital seemed to exist for the pathological laboratory. They should remember that the pathological laboratory existed for the hospital, not the hospital for the laboratory. There was also a false idea of economy; hospitals were apt to be compared on the basis of the cost of maintenance. The only true basis for comparison was that of work done. In some of the private hospitals the cost of maintenance was more than double that of several of the public hospitals. The work in the private hospitals was often so superior that it justified the increased cost. In establishing a new hospital a committee was usually sent to an older hospital where traditions had been established to find out how it was run and then they endeavored to duplicate conditions. The hospital that was settled in its way of doing things and is the slave of tradition was a dead hospital too often. The active and critical hospital was the better one. A hospital was no longer a place merely for the relief of disease, but social workers had come in and demanded that social justice be done. If social service work was to be done it should be done in addition to and not at the expense of the present hospital work. To sum up, the ideal of the hospital should be to promote economy and efficiency. They should produce results, and whether it cost much or little the work should be well done. There were a few defects common to many hospitals and deserving of consideration. Hospital reports consisted usually of statistical statements of work done. No hospital did all the work that it should do. Many applicants could not gain admission for one reason or another, and this rejected class received no help. There should be one person connected with each hospital whose duty it should be to advise those who were rejected as to where they should go. The hospitals should enumerate the things they had failed to do, as this would give philanthropists the knowledge of the needs that existed. It would help the Health Department to get appropriations for their work, for they had to care for the contagious diseases that were not admitted to general hospitals. There was not a single complete hospital in the city that was one that could accommodate all clinical groups that needed care. For instance a medical case with eye trouble could not be accommodated in an eye hospital, and if the case went to a general hospital there would be no regional specialist. Dr. Goldwater believed that there should be no special hospitals. The special hospital should be in close connection with the general hospital. The ideal hospital should include not only all the clinical groups, but these groups should be in close cooperation with one another. The hospitals should also report in regard to the number of transfers made. Dr. Goldwater referred to Dr. Gerster's plea for paid officials in the hospitals and said that he agreed that it was necessary to give salaries to certain workers. It was especially necessary that the physician who had charge of the admissions should be on a salary and also the radiographer and pathologist should have better salaries than they are now getting. Whenever they asked a man to work for a hospital in a way that did not help him in building up a private practice he should be paid for his time. The day-room represented a special need of the convalescent. It was a waste of capital to take the equipped beds needed for acute cases for the purposes of the convalescent. As hospital work had evolved there had come a need for a larger percentage of nurses. In Roosevelt from 55 to 58 per cent. of the population of the hospital were attendants and 45 per cent. were patients. The number of attendants tended to increase as hospital ideals were raised. Every hospital should have a reserve force of nurses. There was also great need of raising the standard of the other hospital helpers, such as scrub women, ward boys, etc. The public hospitals should pay this class of help as much as the private hospitals did. Men should be so recompensed that they could become decent members of society.

Hospital Accommodation for Infectious Diseases.—Dr. Hermann M. Biggs said that many did not appreciate the difference between a general hospital and a hospital for contagious diseases. The hospital for contagious diseases not only existed for the relief of suffering and the cure of disease, but primarily for the protection of the public

against contagious diseases. There was not sufficient hospital accommodation of this kind in this or any other American city. It was necessary to detain a patient until he was no longer a menace to the public. Since they took the patient without his desire the Board of Health has always felt that they were under obligations to give the best accommodation and food possible, and consequently they had to purchase the best supplies. The difficulties of management were greatly complicated and required special arrangements. There were many mixed infections, in fact the combinations in this respect were almost innumerable. They required a very high character of service and, happily, physicians had improved greatly. The division of the contagious hospitals began under Dr. Lederle's first service. Mayor Low gave his support and $2,000,000 was put at the disposal of the Board of Health for this purpose which was two or three times as much as they had ever had before. Another difficulty with which the contagious hospital had to cope was the difficulty of acquiring land. No one wanted a contagious hospital in his neighborhood. They now had three or four times as much land as they had fifteen years ago. In regard to sanatoriums for the tuberculous the difficulties were very great. The hospital capacity for tuberculous patients in 1902, including wooden buildings, was 500 patients; the recent hospital census showed that they were caring for 1,900 patients. This did not represent what they should be doing. There were large groups of cases for whom no one provided. Whooping cough had not been provided for at all. They took a certain number of cases of measles, when home surroundings were extremely unsanitary, but their facilities for this work were totally inadequate. Eight or ten years ago it was almost impossible to get patients to go to a contagious hospital, but now they went willingly. This was due to a change in management. Visitors were formerly not allowed unless the patient was dangerously ill. Dr. Biggs now believed that the danger of transmitting disease through a second person had been enormously overestimated and when they admitted a patient now they gave the relatives cards of admission and the visiting hours. This had greatly changed the attitude of the tenement population. The problem now was how to keep patients away. In England they allowed one bed for each 1,000 population; on this basis they should have 4,700 beds, while they had only about 1,500, or less than one-third of what they should have. They hoped in the near future to have three or four hundred additional beds, but they would still have far too few. They took a certain number of cases of tuberculosis which they were forced to take. They had taken cases that were insubordinate in general hospitals. The first cases they took were of this character. They would not obey rules in regard to expectoration, etc. It was right for the hospitals to exclude them, but they were the patients most dangerous to the public. Another difficulty of the contagious hospital was the enormous variation in demand. In the early spring they would have five or six hundred more patients than they had proper accommodations for, while in the fall they would have scarcely a hundred cases. They also had the problem of nursing that this variation involved. It was a great expense to carry nurses along so as to have them when they were needed. They no longer depended upon voluntary internes. All members of the staff were paid, even though some of the salaries were very small. The problem of the prevention of tuberculosis had resolved itself into removing the cases from home in many instances. The reports of the Board of Health showed that last year there were 41,000 cases of tuberculosis and during the present year there were 30,000 new cases. A large percentage of these should have sanatorium care. They should have 10,000 beds. When they first took a census of tuberculosis patients there were 600 in institutions, now there were 4,000. The city could not provide and maintain 10,000 beds at the cost of other hospital beds. The Board of Health had consequently purchased a farm at Otisville, where they provided only the most temporary sort of accommodations. While the climate was rigorous the patients were not unfavorably affected. They had begun with 30 patients and now had from 350 to 400. Dr. Biggs said that he had yet to see any case in which harm had been done by exposure to weather and he made this statement only after very careful consideration. They not only took incipient cases, but those in the second and third stages; the only ones excluded were those running a high temperature and likely to be bed cases. He believed that a hospital of the modern type was not only not necessary for them but was actually harmful. In the last stages they, of course, needed warmth and comfort. This should solve the problem of hospital construction for these cases. The cost of hospital accommodation, of procuring all that was necessary or desirable, would be $500 a bed. If they were to have fireproof construction this would mean an increase of 30 to 50 per cent. The patients should do the work of the hospital. At Otisville the ratio of employees to patients was 1 to 10. This was one of the best features of the plan. Dr. Biggs did not think this work of caring for tuberculosis cases should be left entirely to the Board of Health.

The Public Hospital in New York.—Robert W. Hebberd, former Commissioner of Charities, said that, except for overcrowding, the public hospital of New York city was excellent for the sick poor. Of late the administration had been spending more on the hospitals than formerly. There were two evils at present in the public hospitals: the first was overcrowding; there was hardly a hospital in the city not greatly overcrowded every winter. On Blackwell's Island, with a capacity of 600, they had 800 patients last winter. Every available bit of space was occupied. Because of this temporary shacks were suggested, but he thought they were out of place on Blackwell's Island. Consequently good buildings were put up and would soon be open. They did not find that the tuberculous patients on Blackwell's Island did as well in tents. They were mostly third stage patients. There was a great contrast in the condition of those in tents and those in the hospital. Those in the tents lost weight. Mr. Hebberd said that the fact was that a tuberculosis hospital was also a general hospital and needed the facilities of a general hospital. He believed that tuberculosis patients should have regulation hospital accommodations. The other great evil was the poor rate of pay given the hospital helpers. A law had been passed preventing convicts from caring for the sick, but this had little effect, as, at the price paid, only that class of help could be obtained, and the last state was worse than the former as they did not have the supervision over the help now that they formerly had over the convicts. In laying out plans for hospitals and putting up buildings he had sought expert advice from physicians who had given the subject time and study. He thought the Mayor should take an attitude toward the hospitals that would say "We are behind you and want you to do this work right. We will give you all the money you need, but you must account for it and you must do the work."

The Relation of Hospital Reform to Budget Reform.—Dr. William H. Allen of the Bureau of Municipal Research advised the city to segregate its needs so that the community would vote all that it ought to vote to meet its needs. The budget provided for the hospitals in four ways: it exempted private hosptials from taxation; it gave subsidies; it voted $2,000,000 to its own hospitals and to the Departments of Parks and Docks many millions more.

Dr. W. Gilman Thompson, in discussing this subject, said that this was a matter that interested all of the 5,000 physicians in New York City. While there were 62 gen-

eral hospitals, there was not one founded by medical men; there were in the city three medical colleges and not one of them in control of a hospital. There was indication of having cooperative stores which would be a great saving of expense to both public and private hospitals. The hospital situation had entirely changed in the past decade and buildings must be adapted to changed methods of treatment. There was now need of a large department for mechanical therapy and for radiography. This implied space in construction. We were getting very much behind in hospital construction and equipment. The physician could no longer make his diagnosis and let it go at that; he had to be supported by the pathologist, the microscopist, and the radiographer. They had entered on a new era and must meet new demands.

Dr. Biggs, in closing the discussion, said that he did not think Mr. Hebberd was referring to a different class of patients than the one to which he was referring. They did not need the equipment of a general hospital for patients in the last stages of tuberculosis. All one could do was to feed, nurse, and care for them until they died. Dr. Biggs moved that a committee be appointed to consider hospital needs and to present them to the Board of Estimate in the fall.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held May 12, 1910.

Dr. Eli Long, in the Chair.

This meeting was held under the auspices of the Section on Pediatrics with the cooperation of the New York Milk Committee.

The Milk Supply of Copenhagen.—Prof. Bernard Boggild, of the Royal Danish Agricultural College, Copenhagen, Denmark, told how they had solved the milk problem in Copenhagen, the capital of Denmark. This city was the commercial center of Denmark, and had a large trade in grain, wool, butter, leather, etc. In 1890 it had a population of 312,859; with suburbs, 373,123. The milk of Copenhagen was greatly adulterated at that time. G. Busck, a wholesale butter dealer and to-day one of the great merchants of his nation, some thirty years ago noticed that one of his workmen showed signs of concern and abstraction, and learned that the man was worrying about his baby, being afraid that he could not raise the baby unless good milk could be obtained for him. It seemed to Dr. Busck that Copenhagen, the commercial center of the world's greatest dairy trade, should abound in good milk. He then formed the Milk-Furnishing Society of Copenhagen with a capital of about $2,500. To-day the capital was about $150,000. No dairies, farms, or cattle were owned by the Society. This Society had been instrumental in purifying the entire milk trade of Copenhagen, and its influence had reached far beyond into the outlying countries, as well as to Norway, Sweden, and Germany. This Commission commenced operations in 1878; the real aim of its formation was education and sanitary protection; its official motto, "Pure Milk from Sound Cows." Forty farms, with about 5,000 cows, were under a rigid contract with this organization. The farmers bound themselves to feed their milch cattle on certain kinds of fodder, to turn them out to pasture during the season, and to report at once any disease among the animals, the employees, or the family of any one connected with the dairy. The Milk-Furnishing Society of Copenhagen guarded itself against selling not only infected milk, but milk that was even under suspicion of being infected. The dairy-farms were models of cleanliness. Prof. Boggild showed on the screen the well groomed cattle, the well kept stables, the large and small farms, the milkers, the dairies, the wagons used for transportation of the milk, the milk cans with special arrangements for keeping the milk cool, etc. The cattle were groomed before milking. No dry-sweeping of the stables was permitted. The milkers, usually girls, were dressed in special costumes, and the milking force was supposed to use soap, water, and towels frequently. Immediately after milking, the milk was strained, poured into sterilized receptacles, cooled, and placed in a cool chamber. Usually the milk reached the consumer before it was twelve hours old. The milk was only sold in sealed glass bottles. All milk vending was under the supervision of the Board of Health. No dealer could go into the business, nor could any farmer peddle milk, without formally notifying the sanitary police. Occasional visits by the inspectors of the Board of Health and constant supervision by the sanitary police served to keep the dealers up to the prescribed standard. In 1880 out of every one thousand deaths in Copenhagen 219 were of children under one year; in 1890 this figure had been reduced to 198, and the figure was larger than it should have been because of a pandemic of grippe and diphtheria. From 1902-1906 the ratio of infant mortality to total mortality was but 144 in a thousand.

Problems of the Dairymen.—Mr. Raymond A. Pearson, New York State Commissioner of Agriculture, of Albany, N. Y., said that the dairy industry was not only important in Denmark, but in all the countries where dairies existed, but they had imported not only a plan of work and methods from Denmark, but they had even in this country adopted some of their sons who were now occupying permanent and important places in the State. With regard to the problems confronting the dairymen, he called attention to the fact that there were nearly 200,000 farms in the State of New York on which were dairy cows. There were more than 1,500,000 dairy cows in the State. If one should ask the dairyman, "What is the chief problem confronting you?" the majority of them would reply that the chief problem was how to make ends meet. For a long time dairying had not been a highly profitable industry in this State. One might ask why men remained on the dairy farms and continued in this line of work. Many had ceased; there had also been a decreasing number of cows in some sections. But the reason more men were not giving this work up was because they had their capital invested and they could not see how they could change their occupation with their money tied up. Mr. Pearson said he did not wish his hearers to believe that dairying was not profitable on all farms; on some farms they made a good profit. At the same time they were not receiving a fair remuneration for the work done and the capital invested. Some of the farmers to-day were even drawing on their capital. Then again there was a decrease in the fertility of the farms; this was not universal, but it did obtain in certain parts of the State. He asked why the conditions were different to-day from what they were ten years ago. The price of milk had not increased, but the cow's feed, grain, and by-products had gone up in price considerably, even advancing from fifty to seventy-five per cent. during the last half a dozen years. The price of hay had doubled in a very short time. The farmers were grappling with many problems, and they were making strong efforts to increase the yield of milk the cows were giving. The farmers were studying how to increase the strain of their cattle. In the treatment of bovine tuberculosis, the State of New York was rendering a great deal of aid; under the present State law a farmer believing that his cow or cows were tuberculous and wishing to have the State veterinarian, can have one visit and examine the cow or cows free of charge; but the farmer, in return for this service, must sign an agreement that he will keep his herd free of tuberculosis. Last year the State expended $150,000 in this work. This year a larger sum

of money would be available. The farmers had learned that the tuberculosis problem was one that never would be solved until they themselves took active steps toward the solution of it. Another problem confronting the farmer and dairyman was how he might meet the new demands along sanitary lines, the demands of the consumer, the demands of the physicians, the demands of the health officers, the demands of those who made the laws in the interest of public health. It was interesting to note that the consumer was not up to the dairyman when it came to recognizing the real importance and value of better sanitation in dairies. Mr. Pearson, in closing, said he would like to see in this State a movement that was comparable to the movement so widespread in the State of Maine. There it had been made a criminal offense to sell milk obtained from tuberculous cows or from cows that responded to the tuberculin tests.

Raw Milk.—Dr. George W. Goler of Rochester said that Rochester received daily 80,000 quarts of milk from 8,000 cows on seven hundred farms from a maximum distance of 60 miles in three directions. Thirteen years ago the first systematic attempt to improve the milk supply was made under municipal direction. This was done by extending milk inspection into the country, by increasing the number of sanitary inspectors in the city, by making occasional bacteriological examinations of the milk taken from wagons at the time of delivery and by establishing summer milk stations in charge of trained nurses for the sale at cost of milk in nursing bottles for babies. In 1900 systematic bacteriological examinations of the milk were begun and a statement was issued to producers and retailers that milk containing more than 100,000 bacteria per c.c. would be considered evidence that there was something wrong with the production and handling of the milk. The Health Bureau of Rochester is now trying to improve the quality of all of the market milk. The milk inspector is not only an inspector but a teacher and he strives to impress the milk producer with the elementary rules of dairy cleanliness. He shows not only that clean milk has a hygienic value in promoting health and prolonging life, but that the application of the rules had an economic value in prolonging the lives and usefulness of cattle, in saving unnecessary labor and in securing a better market and a more equable share of the profits in the milk business. They endeavored to inspect eight hundred farms from two to five times annually, to collect yearly 3,000 samples for chemical and 1,000 samples for bacteriological examination. They were endeavoring to exercise such a watchful care over the milk that it would be fit for use by children. The inspector carried a score card which insists on four general provisions: a drained barn and yard; not less than three square feet of light per cow; window ventilation from windows hinged at the bottom; the general provisions of cleanliness of stable, cow, milker, cans, and utensils, and upon a milk room separate from the stable. He attempted to explain to the farmer that it was possible to build, and equip a milk room with cement floor, running water, boiler, sinks, sterilizer, and storing box for three hundred dollars. He also showed that it was possible to build a model icehouse holding 30 tons of ice at a cost of not more than seventy-five dollars. The cost of their work did not exceed $6,500 per annum, including the expense of summer milk stations. The cleanliness of the market milk might be shown by taking the average bacterial count of 5,000 samples of milk in the last five years. Forty-five per cent. of the samples contained less than 100,000 bacteria per c.c. Of the 60,000 quarts received into the city 6,000 quarts were pasteurized by two companies. In a way the effect of clean milk on the health of the city might be gauged roughly by the number of epidemics of scarlet fever, diphtheria, and typhoid traceable to milk. During the past ten years there had been one outbreak of scarlet fever with 27 cases and one death; one outbreak of diphtheria with ten cases and one death; and three outbreaks of typhoid fever with 50 cases and five deaths. Last year they began to determine how many of their retailers were selling milk capable of producing naked eye lesions of tuberculosis in guinea pigs. The reacting time of the animals had not yet expired so that they were not prepared to report fully on the work. They had tested or had secured applications for testing more than 20 per cent. of the cattle supplying Rochester and there had been between one and two hundred cattle condemned and killed. The testing had been done by the State Department of Agriculture. In the thirteen years from 1884 to 1897 inclusive, during which no systematic milk work was done, the total number of deaths under one year of age was 6,306; the deaths between one and five years of age were 3,304, making a total of deaths from birth to five years of age of 9,610. For the thirteen years' period from 1897 to 1909, inclusive, the total number of deaths of children under one year of age was 4,641, and deaths from one to five years of age 2,080, making a total of 6,721. In the first period not all the deaths were reported; in the last period they had reported the death of every child born at term who breathed. The mortality showed a diminution of 30 per cent. for the last period. They had endeavored to raise the standard of all market milk. If the producers knew that the milk was to be treated in any way they would not be so careful to keep dirt out of it.

Bovine Tuberculosis.—Dr. William H. Park, Department of Health, New York City, said that the part assigned him in the symposium was the amount of tuberculosis in man and in cattle. It required some time before the disease could be eradicated in cattle and even in the best herds they found cases of tuberculosis which must be cleaned out. It was a serious problem for the farmer, that when a certain percentage of his cattle had been eliminated, say six, seven, eight, or ten per cent. he must buy more cattle. In this State it was almost impossible to obtain cattle that were free from tuberculosis; a certain percentage of them would become infected year by year, and this of course meant a loss to the farmer. Wherever one went in this State tuberculosis would be found among the cows. The farmer would of his own accord eradicate tuberculosis among the cows if he could. Cows with tuberculous udders were rare; yet if one cow had tuberculous udders, she could contaminate the entire milk supply. Dr. Theobald Smith of Boston and others had demonstrated the differences between the bacillus that caused bovine and human tuberculosis. Bovine tuberculosis in man was always a negligible quantity. The bacillus from cattle grew with great difficulty in the ordinary media; that from the human grew with great rapidity in ordinary media. They now had other methods to determine whether they were dealing with the bovine or human bacillus of tuberculosis. Dr. Park presented some interesting charts. The first chart was from the reports of German, English, and other observers. It showed the number of bovine and human tuberculosis cases and other points of interest, as follows: There were 491 cases, the largest number being of the pulmonary type and all human, none bovine in either children or adults. In the cases of cervical adenitis there were 8 cases of the human type in patients over sixteen years, 10 of the human type between the ages of five and sixteen, and 12 of the bovine type, while under five years 7 were of the human and 7 of the bovine types. Among the generalized cases, in adults over sixteen, 6 were of the human type; between the ages of five and sixteen, 3 were of the human and 3 of the bovine type; under the age of five, 11 were of the human and 15 of the bovine types. With meningitis, in those over sixteen years, there were 20 cases of the human type: between

the ages of five and sixteen, there were 8 of the human and 1 of the bovine type; under five years there were 37 of the human and 1 of the bovine type. With bones and joints involved, there were, in those over sixteen years, 16 of the human type; in those between sixteen and five years, there were 15 of the human and 1 of the bovine type; of those under five years, there were 14 of the human type. The abdominal cases showed in those over sixteen years 6 of the human type; between the ages of sixteen and five, there were 3 of the human and 6 of the bovine type; under five years there were 4 of the human and 9 of the bovine type. In a second chart containing over 400 cases there were in those above the age of sixteen, of the pulmonary type, 278 of the human type; among those between the ages of sixteen and five there were 8 of the human type; in those under five years there were 5 of the human type. In the cases of cervical adenitis there were in those over sixteen years 10 cases of the human type; in those between sixteen and five years, there were 23 of the human and 8 of the bovine type; in those under five years, there were 5 of the human and 12 of the bovine type. Among the generalized cases there were, among those over sixteen years, 2 of the human type; in those between sixteen and five years there was 1 of the human type; in those under five years, there were 13 of the human and 5 of the bovine type.

With meningitis, among those over sixteen, there was 1 of the human type; among those under five years, there were 32 of the human and 2 of the bovine type. With bones and joints involved, there was 1 among those over sixteen years; between the ages of sixteen and five there were 10 of the human type; under the age of five, there were 6 of the human type. The abdominal cases showed that in those over sixteen years, there was 1 of the human and 1 of the bovine type; among those between sixteen and five years, there was 1 of the human and 1 of the bovine type; under five years there were 3 of the bovine type. Dr. Park emphasized the fact that bovine tuberculosis was a negligible quantity. Six-tenths of one per cent. of bovine tuberculosis occurred among the adults, whereas 27 per cent. occurred among the children. He believed that the whole milk should be heated at the homes; then it is a safe and wholesome product. The aim was to get milk that was clean. The pasteurization of milk was a question for each city to decide for itself.

Dr. Roland G. Freeman said that he was interested particularly in the pictures showing the cow stables and in comparing what they were doing in Denmark with what to-day they were doing in this country. The movement for clean milk started in Denmark long before it started in this country; it was started there in 1878, whereas here it was not started, that was the real movement for clean milk, until 1890. The work of milking cows by women was a great improvement and done far better and cleaner than when it was done by man; women's hands were not so difficult to keep clean. With regard to the bacterial control of milk, any test without an inspection of the milk was worse than useless.

Dr. A. Jacobi said that what had been told them was that the best milk was still doubtful milk; even the so-called certified milk could not be called an absolutely clean milk. All milk, in order that it might be made safe for feeding infants and children, must be pasteurized; this was a fact that had been known for years and years. The only safety for the children of the present, not for the children of the future, was in the use of boiled milk. The milk should be placed over the fire and brought up to the boiling point; when it began to bubble it should be removed. Any milk prepared in this way he considered safe for infants and young children. Until New York City could obtain better milk the only safety lay in bringing the milk to the boiling point.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Michigan State Board of Registration in Medicine.

Ann Arbor, June 14, 15, and 16, 1910.

ANATOMY.

1. Give the origin, insertion, and action of the rectus femoris.
2. Describe the scapula, and name the muscles attached to it.
3. Describe the collateral circulation after ligature of the common carotid artery.
4. Describe the inferior maxillary bone, and name the muscles attached to it.
5. Describe the deep palmar arch, and give its formation.
6. On examination of the under part of the brain, what structures and anatomical features will you observe?
7. Give the arterial and nerve supply of the pharynx, and mention the openings into it.
8. Describe the great superficial petrosal nerve.
9. Describe the solar plexus and give its situation.
10. Describe the knee joint.

HISTOLOGY AND EMBRYOLOGY.

1. Describe the blood.
2. Does fetal blood and blood pressure differ from that of the mother? If so, how?
3. Describe the structure of the lungs.
4. Give the histology of the thyroid gland.
5. Describe the kidney.

PHYSIOLOGY.

1. What are the manifestations of cell life? Metabolism? Explain significance, and give classification.
2. Name the nerve centers which regulate intestinal peristalsis. Describe their action.
3. Name end products resulting from digestion of the three principal types of food, and explain how and by what channels they enter the circulation.
4. What is the physiological significance of the patellar reflex, and through what nerves is it accomplished?
5. Name the varieties of blood that circulate through the liver. State the source and give the function of each.
6. What purpose is served in boiling starchy foodstuffs, and when can a given amount be said to have been completely digested?
7. Why do we breathe? What sounds are heard on listening to the chest? Where is the respiratory center located?
8. Give three examples illustrating the value of a knowledge of physiological chemistry.
9. Describe the special function possessed by each nerve factor concerned in a vasomotor action, and state how either affects arterial tension.
10. What changes take place in the composition of blood as it passes through the kidneys?

CHEMISTRY AND TOXICOLOGY.

1. Name the constituents of the atmosphere. Is air a mechanical mixture or a chemical combination of its constituents, and why? What part does carbonic acid play as regards vegetation? State the laws of gaseous diffusion.
2. Give the equations showing the action of sulphuretted hydrogen on solutions of copper sulphate and on alkaline hydroxide; also equations covering the production of carbon dioxide.
3. What is the difference between atoms and molecules of the elements? What volume does the molecule occupy in the gaseous state? Give examples.
4. Give the characteristics of good drinking water, with method of determining same.
5. Name the more important of the petroleum products and their uses.
6. Name three aromatic hydrocarbons, with formulæ.
7. Describe the groups of the compound proteids.
8. Give a list of the xanthin and creatinin groups of leucomaines.
9. Symptoms and treatment of poisoning by poison ivy. What active principle is involved?
10. Symptoms and treatment of poisoning by strychnine.

MATERIA MEDICA AND THERAPEUTICS.

1. Name the toxic and physiological action of atropine and morphine.
2. What is the true and toxic action of calomel and iodide of potassium?

3. What are the potassium salts used in medicine?
4. What are depresso motors? Excito motors? Oxytoxics? Mydriatics? Alteratives? Give examples of each class.
5. Give examples of drugs which affect the heart action, their doses, and principal actions.

PATHOLOGY.

1. Mention some of the determining causes of disease.
2. Explain the effect of overfeeding upon the body.
3. Mention and define the forms of hemorrhage.
4. What constitutes fatty infiltration? Give etiology and favorite seats.
5. Describe the phenomena of inflammation in vascular tissues.
6. Osteoma: Give general appearance, seats, and structure of.
7. Define glioma. Give its seats, minute structure, and nature
8. By what term do we designate the destruction of red-blood cells? Give etiology.
9. Etiology and pathological anatomy of aneurysm.
10. What is the condition of the kidney in chronic interstitial nephritis? How is the urine affected?

BACTERIOLOGY.

1. Describe the *Bacillus typhosus*, and briefly tell how you would differentiate it from *Bacillus coli communis*.
2. Describe fully the organism recognized as the cause of syphilis.
3. Define immunity, active and passive, natural and acquired.
4. Describe fully the different modes of multiplication in bacteria, and spore formation.
5. What are bacterial enzymes?

PRACTICE OF MEDICINE.

1. Describe the characteristic symptoms and course of scarlet fever.
2. Discuss the diagnosis, symptoms, and treatment of whooping cough.
3. Discuss pericarditis and its treatment.
4. Describe a method of anesthesia you prefer for your patients.
5. Describe the symptoms present in: (*a*) Carcinoma of the stomach; (*b*) gastric ulcer; (*c*) duodenal ulcer.
6. Outline the management of a case of lobar pneumonia.
7. Give in detail your advice to a young patient in the earliest stage of tuberculosis.
8. Mention some drugs which lower blood pressure, and give a theory of their action.
9. Give the therapy of acute cystitis.
10. Mention some complications which may follow typhoid fever.

OBSTETRICS.

1. What is "hour-glass contraction"? How would you overcome it to remove adherent placenta?
2. Describe placenta prævia, and how would you treat it during labor?
3. How would you manage a face presentation?
4. Give the cause, treatment of puerperal eclampsia, insanity, and septicemia.
5. How would you diagnose a shoulder presentation, and its correction?

GYNECOLOGY.

1. Describe the uterus, its shape, dimensions, cavities, parts, openings, structure, lining, membranes, secretions, ligaments, nerves, etc.
2. Describe the vulvovaginal glands.
3. What are the causes of downward displacements of the uterus?
4. What is the organ most frequently affected in tuberculosis of the pelvis?
5. What are the symptoms of extrauterine gestation?

SURGERY.

1. Give the most approved methods of treatment of hemorrhoids.
2. Describe fully the best method of procedure in case of recurring dislocation of the sternal end of the clavicle.
3. What signs and symptoms are always present in fractures? What are usually present?
4. Describe the best management of penetrating wounds of the skull caused by gunshot.
5. Give full description of operation of thyroidectomy.
6. Give the conditions under which resection of the bowel should be undertaken.
7. What is general anesthesia? How is it produced? What are the dangers to be avoided, and how?
8. Under what condition should the common carotid be ligated? Describe the operation.
9. What is surgical shock, and how would you relieve it?
10. Under what circumstances should appendicostomy be resorted to? Give technique of operation.

HYGIENE.

1. What is the difference between disinfectants and germicides, and how do they severally act in preventing the spread of contagious and infectious materials.
2. What disease-carrying bacilli may be conveyed to the system by the ingestion of milk? What are the microscopic characteristics of such bacilli?
3. Mention three satisfactory disinfectants, and give indications for their use.
4. What deleterious gases accumulate in imperfectly ventilated sleeping rooms?
5. Name five diseases requiring quarantine regulations, and state the time necessary for each.

EYE, EAR, NOSE, AND THROAT.

1. Describe, in detail, how you would treat a chemical burn of the eyeball.
2. Give indications and contraindications for tracheotomy and intubation.
3. Give causes, symptoms, prognosis, and treatment of chronic suppurative otitis media.
4. Differentiate between trachoma and conjunctivitis. Give prognosis and treatment for trachoma.
5. Describe, in detail, the syphilitic conditions that may be found in the nose and throat.

MEDICAL JURISPRUDENCE.

1. Define: (*a*) Medical jurisprudence; (*b*) expert testimony; (*c*) civil malpractice; (*d*) criminal malpractice.
2. Give post-mortem appearances due to: (*a*) Asphyxia; (*b*) drowning; (*c*) strangulation.
3. Describe a proper medical investigation in a suspected case of homicide.
4. How would you determine whether a wound or burn was inflicted before or after death?
5. What is insanity? Distinguish between intellectual and moral insanity.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

MICHIGAN STATE BOARD OF REGISTRATION IN MEDICINE.

Ann Arbor, June 14, 15, and 16, 1910.

ANATOMY.

1. RECTUS FEMORIS. *Origin:* Anterior inferior, spine of ilium; and groove above the brim of the acetabulum. *Insertion:* Into the patella. *Action:* It helps to extend the leg upon the thigh and aids in supporting the pelvis and trunk upon the femur.

2. See Cunningham's "Anatomy" (1909), page 183; or Gray's "Anatomy" (1908), page 172. The *muscles attached* are: Subscapularis, supraspinatus, infraspinatus, trapezius, deltoid, omohyoid, serratus magnus, levator anguli scapulæ, rhomboids major and minor, triceps, teres major and minor, biceps, coraco-brachialis, and pectoralis minor.

3. After ligature of the common carotid artery the collateral circulation is: (1) The superior thyroid (of external carotid) with inferior thyroid (of subclavian); (2) the profunda cervicis (of subclavian) with the arteria princeps cervicis (of occipital); (3) the transversalis colli with the occipital; (4) branches of the two vertebrals, with branches of the two external carotids; (5) by the circle of Willis.

4. See Cunningham's "Anatomy" (1909), page 142; or Gray's "Anatomy" (1908), page 122. The *muscles attached* are: Levator menti, depressor labii inferioris, depressor anguli oris, platysma myoides, buccinator, masseter, orbicularis oris, geniohyoid, geniohyoglossus, mylohyoid, digastric, superior constrictor of pharynx, temporal, internal and external pterygoids.

5. See Cunningham's "Anatomy" (1909), page 836; or Gray's "Anatomy" (1908), page 660.

6. *On the under surface of the brain* there are: (1) *In the middle line:* Longitudinal fissure; Rostrum and peduncles of corpus callosum; Lamina cinerea; optic commissure; Pituitary body; Infundibulum; Tuber cinereum; Corpora albicantia; Posterior perforated space; Pons; Medulla. (2) *On each side of the middle line:* Frontal lobe; Olfactory bulb, tract, and roots; Anterior perforated

space; Fissure of Sylvius; Optic tracts; Crusta; Temporal lobe; Hemisphere of cerebellum.

7. PHARYNX. *Arterial supply:* Ascending pharyngeal, pterygo-palatine, superior or descending palatine, superior thyroid, descending palatine, and tonsillar. *Nerve supply:* From pharyngeal plexus (from vagus, glossopharyngeal, and sympathetic) and from external and recurrent laryngeal nerves. *Openings:* Two posterior nares, two Eustachian tubes, mouth, larynx, and esophagus.

8. See Cunningham's "Anatomy" (1909), page 687; or Gray's "Anatomy" (1908), page 1048.

9. See Cunningham's "Anatomy" (1909), page 712; or Gray's "Anatomy" (1908), page 1091.

10. See Cunningham's "Anatomy" (1909), page 297; or Gray's "Anatomy" (1908), page 336.

HISTOLOGY AND EMBRYOLOGY.

1. The blood is a fluid tissue composed of cellular elements (red corpuscles, white corpuscles, and platelets) and intercellular substance, or liquor sanguinis, or plasma. The *red blood corpuscles* are biconcave discs, about 1-3200 of an inch in diameter; they are nonnucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They are elastic and soft, and their shape is changed by pressure, but is promptly regained on the removal of the pressure. Their color is yellowish. They contain hemoglobin.

The *leucocytes,* or *white blood cells,* are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into: (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain; it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells.

The *platelets* are very small, colorless, irregularly shaped bodies; about one-fourth the diameter of a red cell. They vary in number from 200,000 to more than 500,000 per cubic millimeter.

2. *Fetal blood* has a lower specific gravity; the red cells vary greatly in size and shape, are nucleated, and are deficient in hemoglobin; the white cells have a different proportion of their various kinds, the mononuclears preponderating. With regard to *fetal blood pressure,* nothing definite is known.

3. See Cunningham's "Anatomy" (1909), page 990; or Gray's "Anatomy" (1908), page 1403.

4. See Cunningham's "Anatomy" (1909), page 1217; or Gray's "Anatomy" (1908), page 1490.

5. See Cunningham's "Anatomy" (1909), page 1138; or Gray's "Anatomy" (1908), page 1426.

PHYSIOLOGY.

1. The *manifestations of cell life* are: Movement, ingestion, assimilation, excretion, growth, irritability, and reproduction. *Metabolism* is the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Assimilative, or constructive (anabolism); and (2) destructive (katabolism).

2. Intestinal peristalsis is regulated by: (1) The vagus, which stimulates; and (2) branches of the sympathetic system, by the solar and lumbar plexuses, and the splanchnics; the effect of the sympathetic system is inhibition. (3) The rôle of the plexuses of Auerbach and Meissner is not known.

3. *Proteids* are converted into proteoses and peptones in the stomach, and in the small intestine (by the action of pepsin and trypsin, respectively).

Carbohydrates are converted (slightly) into dextrin and sugar in the mouth, by the action of the ptyalin of the saliva; also in the small intestine (by the action of amylopsin) into maltose.

Fats are emulsified and saponified in the small intestine by the action of steapsin. Bile also has some slight effect on starches and fat.

The products of digestion find their way into the blood by two routes: (1) By the blood-vessels of the gastrointestinal tract, which unite to form the portal vein, and (2) by the lymph vessels of the small intestine, which converge to empty into the thoracic duct. The water, inorganic salts, proteids, and sugar go by way of the portal vein to the ascending vena cava; the fats go by way of the thoracic duct to the junction of the left subclavian and internal jugular veins.

4. The patellar reflex is generally present in health. The afferent nerve is the anterior crural; the efferent nerve is also the anterior crural.

5. In the liver there is the blood in: (1) The *hepatic artery* (branch of celiac axis) which supplies Glisson's capsule, walls of the bile ducts, and in general serves for the nutrition of the organ. (2) The *hepatic vein,* which empties into the inferior vena cava; it arises in the liver, and takes the blood away from the liver. (3) The *portal vein,* which takes the absorbed products of digestion from the gastric, splenic, superior mesenteric, and inferior mesenteric veins to the liver.

6. *Boiling* breaks the starch grains, bursting the cellulose, and thus allowing the digestive juices to come more readily in contact with the granulose. The conversion of the starch into sugar takes place more rapidly.

A given amount of starch may be said to have been completely digested when no starch is left, it having all been converted into sugar. In the test tube this can be ascertained by the iodin test showing the absence of starch, and Fehling's test showing the presence of sugar.

7. The object of respiration is the interchange of gases in the lungs, so that oxygen may be introduced and carried to the tissues, and carbon dioxide may be expelled from the body. Two respiratory sounds are heard on listening to the chest, the inspiratory and expiratory. The respiratory center is located in the medulla.

8. *Three examples of value of knowledge of physiological chemistry:* (1) That albumin is coagulated by heat; (2) that glucose will reduce alkaline copper sulphate solution; (3) that pepsin will only exert its proteolytic action in an acid medium.

9. The nerves concerned in a *vasomotor* action are: (1) The *vasoconstrictor,* which causes constriction of the blood-vessels and increase blood pressure; and (2) the *vasodilator,* which causes dilatation of the vessels by inhibiting the action of the vasoconstrictors, and lower blood pressure.

10. As the blood passes through the kidneys it loses: Water, salts, urea, carbon dioxide, and extractives.

CHEMISTRY AND TOXICOLOGY.

1. The *constituents of the atmosphere* are: Oxygen, nitrogen, carbon dioxide, water vapor, ammonia, argon, etc. Air is a mixture, and not a definite chemical compound. *Proof:* (1) The composition is not constant; (2) the proportion of its constituents bears no relation to their atomic weights; (3) when air is absorbed by water and then expelled, the ratio of the nitrogen and oxygen is not the same as in the original air; (4) when oxygen and nitrogen are brought together in proper proportions there is no chemical action, nor is heat given off or absorbed, and yet the resulting mixture has all the properties of air. Carbon dioxide is the food of vegetables, and is by them utilized for the building up of complex organic compounds. *Diffusion of gases:* If two gases be brought in contact with each other they will quickly mingle so as to make a uniform mixture. A similar diffusion will take place if they are separated by a porous membrane or partition. *Graham's law of diffusion* is: The velocity of diffusion of different gases is inversely proportional to the square roots of their densities.

2. $H_2S + CuSO_4 = CuS + H_2SO_4$
$H_2S + KHO = H_2O + KHS$
$CaCO_3 + 2HCl = CaCl_2 + CO_2 + H_2O$
$2NaHCO_3 + \text{heat} = Na_2CO_2 + CO_2 + H_2O$
$2CO + O_2 = 2CO_2$

3. An *atom of an element* is the smallest particle of that element which can enter or leave a chemical reaction. A *molecule of an element* is the smallest particle of that element which can exist free.

The formula weight of the molecule of a gas in grams occupies a volume of 22.4 liters. Thus O_2 represents 32 grams of oxygen, which will occupy 22.4 liters; and NH_3 represents 17 grams of ammonia, which will also occupy 22.4 liters.

4. *Characteristics of a good drinking water:* (1) It should be clear and limpid. Cloudy and muddy waters should be avoided. (2) It should be colorless. A greenish or yellowish color is usually due to vegetable or animal matter in solution or to organisms. (3) It should be odorless; especially free from sulphuretted hydrogen or putrefactive animal matter. (4) It should not be too cold, but should have a temperature of from 46° F. to 60° F. (5) It should have an agreeable taste; neither flat, salty, nor sweetish. A certain amount of hardness and dissolved gases give a sparkling taste. It should contain from 25 to 50 c.c. of gases per liter, of which 8 to 10 per cent. is carbon dioxide and the rest oxygen and nitrogen. (6) It should be as

free as possible from dissolved organic matter, especially of animal origin. (7) It should not contain too great an amount of hardness. A certain quantity of saline matter is necessary, however, to give it a good taste. It should not contain over three or four parts of chlorine in 100,000 parts of water.—(From Bartley's *Chemistry.*)

5. *Petroleum products:* Cymogene (used in ice machines); rhigolene (used to produce cold, and as an anesthetic); gasolene and petroleum ether (used for making "air gas"); naphtha (used as a solvent for fats and rubber); benzine (used for varnishes and paints); kerosene (used for illuminating purposes); lubricating oil (for lubricating machinery); paraffin (for making candles).

6. *Three aromatic hydrocarbons:* (1) Benzene C_6H_6; (2) Phenol, C_6H_5OH; (3) Salicylic acid, $C_6H_4OH.COOH$.

7. Compound proteids are composed of a single proteid united to some non-proteid body. The chief groups are: (*a*) *Hemoglobins*—decomposable into an albumin and a crystalline pigment or chromogen. (*b*) *Nucleoproteids*—yield nucleic acids and native albumins on decomposition. Nucleohiston, etc. (*c*) *Glycoproteids*—decomposable into a reducing substance and a native albumin. Mucin, mucoids, phosphoglycoproteids.

8. *Xanthin group of leucomaines:* Adenin, hypoxanthin, guanin, xanthin, heteroxanthin, paraxanthin, carnin, pseudoxanthin, spermin. *Creatinin group of leucomaines:* Creatin, creatinin, xanthrocreatinin, crusocreatinin, amphicreatinin.

9. Poison ivy. *Symptoms of poisoning:* "When applied to the skin it causes, after a few hours, an intense itching and burning, followed by swelling of the skin of the affected parts, with papular eruption or slight vesication, terminating after a few days in desquamation."

Treatment: "An alcoholic solution of lead acetate usually gives prompt relief. If itching is severe it may be combined with opium. Painting the parts with ichthyol is successful with many, as is the application of fluid extract of grindelia robusta. Weak alkaline solutions have given excellent results."—(Riley's *Toxicology.*)

The *active principle* is toxicodendrol.

10. *Symptoms of poisoning by strychnine:* A sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours. *Treatment:* "The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible." (Witthaus' *Essentials of Chemistry.*)

PATHOLOGY.

1. *Determining causes of disease:* Traumatism, temperature (heat, cold, burns), electricity, environment, poisons, autointoxication, food, parasites, and micro-organisms.

2. *Effect of overfeeding:* Indigestion, disturbed metabolism, increase of urea, increase of fat or glycogen, obesity, fatty infiltration or degeneration, gout, diabetes, anemia.

3. *Hemorrhage* is the escape of all the constituents of the blood from the heart or blood-vessels. *Forms:* According to the source of the flow, it may be *cardiac, arterial, venous,* or *capillary.* Arterial hemorrhages may be *primary* (occurring at the time of injury), *intermediate* or *reactionary* (occurring within twenty-four hours of the injury), and *secondary* (occurring later, even some days after the injury). *Petechiæ* are minute, circumscribed hemorrhages, generally subcutaneous; when larger, they are called *ecchymoses,* or *extravasation,* or *sugillation;* a *hematoma* is a collection of blood in a solid tissue.

4. *Fatty infiltration* consists in the deposition of fat from the circulation between the cells of which a tissue is composed. *Etiology:* Heredity, excessive nutrition, digestive disorders, lack of exercise, anemia, alcohol, diminished oxidation, high external temperature. *Seats:* Beneath skin and serous membranes, in the fascia, in areolar connective tissue, mesentery, omentum, liver, heart, and kidneys.

5. See Rose and Carless' "Surgery" (1908), page 31; or Da Costa's "Surgery" (1908), pages 73 and 76.

6. Osteoma. *General appearance:* There are two forms, exostoses and osteoma proper. The former has its surface irregular and nodular, and has the consistency of bone. The latter is more rounded and lobulated. *Seats:* Bone, cartilage, connective tissue near the bones, serous membranes, and organs such as parotid gland and testicle. *Structure:* Osteoma resembles bone tissue, but cartilage is apt to be mixed with it. Softening and other secondary degenerative changes may occur, and other tumors are apt to be associated with it (chondroma, fibroma, and sarcoma).

7. Glioma. *Seats:* Brain, spinal cord, and retina. *Structure:* It consists of cells containing rounded or oval nuclei, with very little protoplasm, and fine protoplasmic extensions which interlace and form an intercellular reticulum, giving a granular appearance. The number of the cells and the density of the intercellular network vary. As a rule, the cells are larger than neuroglia cells, and sometimes they contain several nuclei. The tumor is generally quite vascular, and occasionally teleangiectatic vessels may be observed. *Nature:* It is benign, but dangerous, on account of pressure; growth is slow, but it may become sarcomatous.—(From Stengel's *Pathology.*)

8. Destruction of red blood cells is called: Hemocytolysis, or hemolysis. *Etiology:* It occurs in the liver; it may result from burns, also from infections and toxic agents (such as potassium chlorate); malaria, pneumonia, and other diseases may cause it.

9. See Rose and Carless' "Surgery" (1908), page 307; or Da Costa's "Surgery" (1908), pages 359 and 356.

10. See French's "Practice of Medicine" (1907), pages 902 and 903; or Osler's "Practice of Medicine" (1909), pages 695 and 697.

BACTERIOLOGY.

1. *Bacillus typhosus* is a rod-shaped organism, with rounded ends, is from 2 to 4 microns in length, and about three-fourths of a micron in breadth; it does not stain by Gram's method, but stains with all the anilin dyes; it has flagella, no spores, is aërobic and facultative anaërobic, and is motile.

To distinguish the typhoid bacillus from the colon bacillus: (1) On gelatin plates, the colonies of typhoid develop more slowly than those of colon bacillus. (2) The colon bacillus causes fermentation with production of gas in media which contain sugar; the typhoid bacillus does not. (3) The colon bacillus produces a strong acid reaction and coagulates milk within twenty-four to forty-eight hours; the typhoid bacillus does not coagulate milk. (4) In peptone solution the colon bacillus produces indol; the typhoid bacillus does not. (5) The typhoid bacillus gives the Widal reaction with typhoid serum; the colon bacillus does not.

2. The cause of syphilis is the *treponema pallidum.* It is a very slender spiral, about 4 to 20 microns in length, with very close and regular turns, the curves vary in number from three or four to twelve or twenty. At each pole is a fine flagellum. It can move forward and backward, and also rotate on its axis. It is not settled whether division is transverse or longitudinal. It has not yet been cultivated on artificial media.

3. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic bacteria. Immunity may be either natural or acquired.

Natural immunity is this power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired immunity is this resistance acquired: (1) By a previous attack of the disease caused by the bacteria, or (2) by the person being made artificially insusceptible. The conditions which give immunity from the pathogenic action of bacteria are: (1) A previous attack of the disease; (2) inoculation, with small quantities of bacteria, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

Active immunity follows an attack of a certain disease and secures immunity for that alone; or it follows inoculation of a virus weaker than necessary to cause the typical disease; or it follows inoculation by bacterial products apart from the organisms themselves.

Passive immunity is the term applied to the effect of a serum derived from an immunized animal and injected into one not immune.

4. Bacteria multiply by fission. A bacterium about to divide seems to be larger than normal, and if it is a coccus it becomes more ovoid; changes occur first in the nucleus, and the bacterium just falls in two. It has been calculated that a single bacterium could, by fission, produce two in one hour. Fortunately, they seldom obtain food enough to keep up this process for any length of time.

Spore formation is not so much a method of multiplication as of continuance of the life of the individual bacterial cell; it is a process by which the organism enters a stage in which it can better resist certain deleterious influences, such as high temperature, desiccation, lack of nutrition. It occurs chiefly in bacilli. There are two forms: *Endospores* and *arthrospores.* The former are true spores.

5. *Bacterial enzymes* are enzymes or ferments produced by bacteria, and which cause certain of the chemical ef-

fects supposed to be due to the bacteria. The curdling of milk is due to a bacterial enzyme rather than to a micro-organism directly.

PRACTICE OF MEDICINE.

1. See French's "Practice of Medicine" (1907), page 317; or Osler's "Practice of Medicine" (1909), page 132.

2. See French's "Practice of Medicine" (1907), page 202; or Osler's "Practice of Medicine" (1909), page 149.

3. See French's "Practice of Medicine" (1907), page 557; or Osler's "Practice of Medicine" (1909), page 775.

4. See Rose and Carless' "Surgery" (1908), page 1323; or Da Costa's "Surgery" (1908), page 1031.

5. *Gastric ulcer* is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

Gastric carcinoma does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

In *duodenal ulcer* the pain is apt to be more to the right, and to occur at an interval of two or three hours after meals; the hemorrhages will be intestinal, and the blood will be passed by way of the bowels, and not vomited. In many cases the symptoms are identical with those of gastric ulcer.

6. See French's "Practice of Medicine" (1907), page 174; or Osler's "Practice of Medicine" (1909), page 189.

7. See French's "Practice of Medicine" (1907), page 391; or Osler's "Practice of Medicine" (1909), page 352.

8. *Drugs which lower blood pressure:* Amyl nitrite, sodium nitrite, spirit of nitrous ether, nitroglycerin. They act by producing dilatation of the blood-vessels.

9. See Rose and Carless' "Surgery" (1908), page 1192; or Da Costa's "Surgery" (1908), page 1135.

10. *Complications which may follow typhoid fever:* Relapses, indigestion, constipation, diarrhea, perforation of intestine, peritonitis, hepatic abscess, cholecystitis, gallstones, hypertrophy of spleen, paralysis, typhoid spine, neuritis.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 664.

2. See Williams' "Obstetrics" (1909), pages 809 and 815; or Hirst's "Obstetrics" (1909), pages 572 and 577.

3. If the chin is presenting anteriorly, expectant treatment may suffice; but care must be taken to observe that the chin does not rotate backward. Spontaneous version may occur, and the presentation becomes a vertex one. Failing this, or as a means of favoring this, postural treatment, such as Walcher's position, has been recommended. If, in spite of this, engagement has not occurred, cephalic version is indicated, care being taken not to rupture the membranes. If this is not successful, podalic version should be tried. If, after all these manipulations the child is still alive and the head is engaged, symphyseotomy is indicated; if the child is dead, craniotomy should be performed.

4. PUERPERAL ECLAMPSIA. The *causes* may be: Uremia, albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are renal disease, and imperfect elimination of the skin, bowels, and kidneys. The line of *treatment* laid down by Edgar is as follows: For *preventive treatment:* (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ. The *curative treatment includes:* (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

And see Williams' "Obstetrics" (1909), pages 915 and 852; or Hirst's "Obstetrics" (1909), pages 256 and 764.

5. See Williams' "Obstetrics" (1909), pages 790 and 802; or Hirst's "Obstetrics" (1909), pages 426 and 433.

GYNECOLOGY.

1. See Cunningham's "Anatomy" (1909), page 1187; or Gray's "Anatomy" (1908), page 1498.

2. See Cunningham's "Anatomy" (1909), page 1198; or Gray's "Anatomy" (1908), page 1495.

3. CAUSES OF DOWNWARD DISPLACEMENTS OF THE UTERUS: (1) *Pressure from above* (pelvic or abdominal tumors, ascites, tight or heavy clothing, straining at stool, muscular exertion, fecal accumulations, habitual overdistention of the bladder); (2) *weakening and relaxation of the uterine supports* (subinvolution, senile atrophy of pelvic floor, abnormally large pelvis, increased weight of uterus, puerperal traumatisms, pressure from above, traction from below); (3) *increased weight of uterus* (congestion, subinvolution, metritis, pregnancy, fluid in the endometrium, uterine tumors); (4) *traction from below* (vaginal cicatrices, falling of pelvic floor, contraction and congenital shortening of vagina, tumors of cervix or vagina).—(From Dudley's *Gynecology.*)

4. In tuberculosis of the pelvis the organ most frequently affected is the Fallopian tube.

5. "When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua in part or whole Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*"—(*American Text-Book of Obstetrics.*)

SURGERY.

1. See Rose and Carless' "Surgery" (1908), pages 1145 and 1151; or Da Costa's "Surgery" (1908), page 1014.

2. See Rose and Carless' "Surgery" (1908), page 618; or Da Costa's "Surgery" (1908), page 586.

3. See Rose and Carless' "Surgery" (1908), page 470; or Da Costa's "Surgery" (1908), page 435.

4. See Rose and Carless' "Surgery" (1908), page 751; or Da Costa's "Surgery" (1908), page 712.

5. See Rose and Carless' "Surgery" (1908), page 900; or Da Costa's "Surgery" (1908), page 1072.

6. *Indications for resection of bowel:* Strictures of intestine, gangrene of intestine, extensive injury of intestine, tumors of intestine, tuberculosis of intestine, injury to the vessels supplying intestines, some cases of intussusception, and artificial anus.

7. See Rose and Carless' "Surgery" (1908), page 1325; or Da Costa's "Surgery" (1908), page 1034.

8. INDICATIONS FOR LIGATURE OF COMMON CAROTID: Wounds of either common carotid, external carotid, or internal carotid (and branches of the two latter); in aneurysms; to limit the growth of inoperable tumors, as a temporary procedure. For the operation, see Rose and Carless' "Surgery" (1908), page 331; or Da Costa's "Surgery" (1908), page 415.

9. *Shock* is the name given to a sudden and general depression of the vital powers, due to some strong stimulation (such as injury or emotion) acting on the vital centers in the medulla, and producing vasomotor paralysis. *Treatment:* Place the patient in the recumbent position, with the head low; apply warmth to the body; administer a stimulant, and give a hot saline infusion; morphine, hypodermatically, may be necessary for the relief of pain.

10. *Appendicostomy* is performed to irrigate the colon in cases of chronic ulcerative colitis or chronic dysentery, and in chronic constination. For technique of the operation, see Da Costa's "Surgery" (1908), page 916.

HYGIENE.

1. *Disinfectants* are agents which restrain infectious diseases by destroying or removing their specific poisons; some are germicides, as chlorine; others act by dilution or removal, as soap and water, and fresh air. *Germicides* are agents which destroy bacteria and their germs.

2. The following disease-carrying bacilli may be con-

veyed by milk; Tubercle bacillus, Klebs-Loeffler bacillus of diphtheria, typhoid bacillus, cholera bacillus.

The *tubercle bacillus* is rod shaped, is from 1½ to 3½ microns in length, and about one-third to one-half a micron in breadth, is a strict parasite, is not motile, and has no flagella. It is slightly curved, does not form spores, is not liquefying, is aërobic and nonchromogenic; it resists acids; it grows well on blood serum; stains well by Ehrlich's, Ziehl-Nielsen's, or Gabbett's method; it is Gram-positive.

The *bacillus of diphtheria* is from 2 to 6 microns in length and from 0.2 to 1.0 micron in breadth; is slightly curved, and often has clubbed and rounded ends; occurs either singly or in pairs, or in irregular groups, but does not form chains; it has no flagella, is nonmotile, and aërobic; is noted for its pleomorphism; it does not stain uniformly, but stains well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

The *typhoid bacillus* is a rod-shaped organism, with rounded ends, is from 2 to 4 microns in length, and about three-fourths of a micron in breadth; it does not stain by Gram's method, but stains with all the anilin dyes; it has flagella, no spores, is aërobic and facultative anaërobic, and is motile.

The *cholera bacillus* is a spirillum, actively motile, and with a flagellum at one end; it is curved, has rounded ends, and is about half the length of the tubercle bacillus; it stains readily with ordinary anilin stains, but not by Gram's method; it is easily cultivated on the usual media; it has but slight power of resistance; it liquefies gelatin, and does not produce pigment.

3. Burning is the best disinfectant; then moist heat and dry heat; carbolic acid and mercury bichloride are excellent except in the presence of albuminous material, when chloride of lime or formalin are better; formaldehyde and sulphur dioxide are both good disinfectants.

4. Carbon dioxide; crowd poison; volatile matters from foul mouths, decayed teeth, and the digestive tract; aqueous vapor from the respiration and skin; products of combustion of illuminating substances.

5. *Five quarantinable diseases:* Cholera, yellow fever, smallpox, plague, typhus. For *length of time*, see index to these diseases in French's or Osler's "Practice."

EYE, EAR, NOSE, AND THROAT.

1. *For chemical burns of the eyeball:* The treatment consists in the complete removal of the caustic substance as soon as possible. Solid particles are removed with cotton or forceps. Then the conjunctival sac is washed out with solutions which tend to neutralize the corrosive substance or render it insoluble. In the case of lime, mortar, or caustic alkalies, we flush out with a solution of boric acid; or we may wash out the eye with oil. If the corrosive agent consisted of an acid, the eye is irrigated with a weak solution of sodium bicarbonate. Subsequently we use cold compresses, atropine, and sometimes a bandage. After the loosening of the eschars, we must separate the adhesions frequently. Symblepharon often occurs notwithstanding the greatest care."—(May's *Diseases of the Eye*.)

2. *Tracheotomy is indicated* in diphtheria when intubation does not relieve and the symptoms are urgent; to remove foreign bodies from the larynx that cannot be treated by simple methods; to provide passage for air, in growths, tumors, or abscesses pressing on the larynx and interfering with the proper supply of air; and for edema of the glottis when the intubation tube cannot be introduced.

Intubation is indicated in any obstruction of the larynx which prevents a sufficient amount of air from entering the lungs, such as croup, edema of the glottis, spasm of the larynx, any form of paralysis that lessens the lumen of the larynx, chronic stenosis. *Intubation is not indicated* for the removal of a foreign body, nor for any obstruction too far down to be reached by the shaft of the tube.

3. See Rose and Carless' "Surgery" (1908), page 882.

4. In *conjunctivitis* there are no granules with subsequent cicatricial changes.

Trachoma is an inflammatory condition of the conjunctiva, accompanied by hypertrophy, granule formation, and subsequent cicatricial changes.

Treatment "consists in an attempt to reduce the inflammatory symptoms and secretion, and to check and remove hypertrophy of the conjunctiva, thus shortening the duration and diminishing the liability to conjunctival cicatrization and to sequelæ. This is accomplished either by the use of certain irritating applications, or by mechanical (surgical) means. *Irritating applications:* Sulphate of copper in the form of a crystal or pencil is the favorite local application. Nitrate of silver (1 or 2 per cent. solution), gylcerole of tannin (5 to 25 per cent.), and the alum stick are also employed. *Mechanical (surgical) treatment* includes expression, grattage, excision, curetting, electrolysis, *x*-rays, and galvano-cautery."—(May's *Diseases of the Eye*.)

Prognosis is not favorable; the condition may last for years, and complete recovery is not common.

5. See Rose and Carless' "Surgery" (1908), pages 822, 830, and 871.

MEDICAL JURISPRUDENCE.

1. *Medical jurisprudence* is the application of the knowledge of any of the branches of medicine to the problems and requirements of the law.

In *expert testimony* the witness may give his *opinion* on facts or supposed facts as noted by himself or asserted by others. *Theoretically* this can be done only by those perfectly familiar with the subject in question; but *practically* any (or almost any) physician with a license to practise is accepted as an expert witness.

In *ordinary* testimony the witness testifies only to *facts* which he has seen, or heard, or with which he has become acquainted by personal observation.

Malpractice is a failure on the part of a medical practitioner to use such skill, care, and judgment in the treatment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil* malpractice. But if done deliberately, or wrongfully, or if gross carelessness or neglect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice*.

2. In *death by asphyxia:* Very commonly punctate ecchymoses are visible on the conjunctiva, face, neck, and chest. They are considered by Tardieu to be more frequent in strangulation than in asphyxia from other causes, or than in cases of overstraining, which likewise may lead to them. In the subcutaneous cellular tissue, and in the fascia of the muscles above and below the hyoid bone extravasations are frequently found, as well as on the external surface of the thyroid cartilage and trachea. The lungs vary as regards their vascularity; but on the surface it is common to find pseudomembranous patches, which are due to the rupture of some of the superficial air cells and collection of air bubbles under the pleura. In the substance of the lungs congested patches, or apoplectic extravasations, are often found, varying in size, but larger than those usually found in suffocation.

In *death by drowning:* The surface is pallid, the face appears tranquil, the eyes and mouth being partly open. The skin often has the appearance known as gooseskin, and, if the body has lain upwards of twelve hours in the water, that of the hands and the feet is sodden by imbibition. The most important external sign is the presence on the mouth and nostrils of a fine froth (possibly blood stained), composed of air, mucus, and the medium in which drowning took place; if the body remains three or four days in water, the froth disappears. Exceptionally, fragments of weeds or other small objects may be found tightly grasped in the hands. On opening the thorax the lungs, gray in color, with reddish staining, are seen to be very voluminous, a condition known as ballooning, partly due to infiltration of the lung tissue with some of the medium in which drowning took place, and partly to true edema. The lung substance is inelastic and pits on pressure. On section, fluid and froth resembling that found on the lips exude from the divided air passages. Minute subpleural hemorrhages are not infrequently present, and the pleural cavities may contain fluid. The stomach often contains water or other liquid which was involuntarily swallowed during attempts at respiration. Occasionally some of this fluid is forced by vital action into the intestines. With one exception, the remaining appearances are those met with after death from asphyxia. The exception is constituted by the blood, which is not only dark colored and fluid, as is usual after death from asphyxia, but is also diluted by the imbibition of water from the stomach and lungs.

In *death by strangulation:* The blood is of a dark color, owing to complete reduction of the hemoglobin. The proportion of carbonic acid is increased, and owing to its excess the blood coagulates slowly or imperfectly; hence it remains fluid or forms few and soft coagula. The large veins, the pulmonary artery, and the cavities of the right side of the heart may be distended with dark fluid blood, but this is by no means necessarily the case. The left side is usually empty or nearly so. The lungs may be congested, but are often pallid and anemic, though the dependent parts usually exhibit appearances of hypostatic engorgement. The abdominal viscera, especially the kidneys, are often congested. The appearance of the brain varies; it may be anemic or more or less congested. Special signs characterize special modes of causation of asphyxia.—(From Quain's *Dictionary of Medicine*.)

3. The physician should note the body; and the surroundings, conditions, and circumstances under which it is found. If the body is in a building, he should observe the position and arrangement of furniture, etc., blood, position of body, arrangement of clothes, position and character of weapons, footprints, and finger marks. The body should be examined for signs of violence (wounds, bruises, blood spots); lividities; the presence of rigor mortis, etc. The physician should keep his suspicions to himself, hear all he can, observe all he can, say nothing, and communicate with the coroner or medical examiner.

4. A *wound inflicted during life* is generally characterized by hemorrhage, coagulation of the blood, eversion of the edges, and retraction of its sides. It may also be inferred that the wound was inflicted during life if any of the following are noticed: The presence of inflammation, swelling, pus, or gangrene on the edges of the wound, or if there is any sign of beginning cicatrization.

In *burns* produced *before death:* There is usually a blister, with a bright, red base, and containing a serous fluid, which is albuminous; occasionally there will be no blister if there has been excessive shock; also, there will be a red line of demarcation between the injured and the uninjured parts, and this, being a vital process, is only developed during life. In *burns* produced *after death* there is no true blister, no red base, and gas only is present in place of the serous fluid.

5. According to Taylor, the term insanity is applied to those states of disordered mind in which a person loses the power of regulating his actions and conduct according to the ordinary rules of society. In all cases of real insanity the intellect is more or less affected.

Intellectual insanity refers to those forms which are characterized by hallucinations and delusions, but in which the patient knows right from wrong.

Moral insanity refers to that condition in which the moral perceptions are blunted, and the patient cannot judge a question of right and wrong. As a rule, moral insanity is accompanied with some intellectual disturbance.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. ..
Arizona*	Ancil Martin, Phoenix	Phoenix	Oct. 3

PSYCHOLOGICAL STUDY OF GANGS.

By SIEGFRIED BLOCK, A.M., M.D.,

BROOKLYN, NEW YORK.

In order to deduce conclusions for scientific investigation it is necessary to make a standard "normal" and then note by how much observations differ from this "normal." This is very difficult to determine when we investigate the psychological make-up of human beings. To state that the Columbia freshman is "normal" is hardly fair to the vast majority of the population who are so much inferior intellectually. To grant that this majority with proper education can be brought on a par with the freshman is a rash presumption and must be proved before it can be accepted. Therefore the author prefers to omit any reference to a "normal," and on what is definitely established as fact proposes to investigate from a psychological point of view a group of individuals whose lives are almost in direct contrast to that of a Columbia freshman.

For this purpose one hundred young men members of recognized "gangs" of about the same age as the freshman (17 to 22 years) have been chosen as subjects and tested with the same tests as are regularly given at the university. These subjects were obtained in the following manner: For several years the writer has been connected with the Children's Courts and thus became acquainted with the boys who belong to these "gangs." From these boys the names and addresses of older members of their "gangs" were obtained, and to these an announcement of four cash prizes was made to be divided as follows: one-half point was to be given for each fellow brought to be tested and one-half point for each test actually taken, and one-half point for the highest efficiency in each test. It was insisted that only "gang" fellows would be accepted and that the examiner could find out by examination if dishonesty had been used to get an outsider into the competition. If so, nothing was said, but one-half point deducted.

The last proviso was made only to make the result as exact as possible, but it could not be perfectly controlled. With so many precautions it became necessary to employ nine distinct "gangs," because each one would tire of the monotony of the idea or had some other more interesting engagement, or for the more important reason, they had suspicion that these tests would be kept for future use, somewhat on the order of the rogues' gallery pictures or Bertillon system of measurement of criminals.

Definition.—What is a gang? Many authors have described gangs from either the sociological or the layman's side and it is to be regretted that so little psychological work has been done in this particular. In order to appreciate their importance, their origin, and formation, and their ultimate power a verbatim extract of "The Boy Problem" by Wm. Byron Forbush, Ph. D., page 56, Chapter 3, will aid. He says under "Ways in Which Boys Spontaneously Organize Socially": "The Interests of Infancy are all in the home. This is the parents' unhampered opportunity. During boyhood the home shares with the school the boy's time, but with the development of his social instinct by means of play, new acquaintanceships begin to use the crevices of his time. First he plays at home with a companion or two, then he ventures forth to the ballfield and swimming-hole with a larger group; finally his journeys are farther, his stay is longer, the group is more thoroughly organized, and a mob spirit is apt to arise which passes from unorganized play and sportive frolic to barbarous and destructive deviltry, and we have in the city and country the organized 'gang.' Accounts of doings of these gangs from the comparative innocence of property destruction and hoodlumism to organized theft, assault, and murder appear in the press daily. Hardly less dangerous in tendency are many clubs which more quietly meet indoors."

A recent report of the University Settlement of New York City calls attention to candy stores as informal social centers which lead to the poolroom, the saloon, the cheap show, and the clubroom, and to the "recreation clubs," where a younger member reports, "They have kissing all through pleasure time, and use slang languages," and the members are from 14 to 18. "They don't behave nice between young ladies."

Dr. Henry D. Sheldon's "Questionaire" shows that out of 1,034 responses of boys 10 to 16 years 851 were members of such societies. In "The Young Malefactor" Travis (page 142) states, speaking of the gang instinct and the formation of gangs, "It is such children adventurous, lawless, idle, and truant that naturally form gangs. The other school comrades being at work, these are isolated and form a little clan. Often a whole gang is brought to court and with the gang some not belonging there who happened to be caught with them. It is a well-known fact that either adults or children will do things by gangs which no single member would dream of doing alone. Gangs indulge in pitched battles on the city streets, annoy pedestrians, insult passing women, incite each other to lawlessness and in some cases form little criminal societies pledged to testify in favor of any who are caught and to 'stick by the gang' in every possible way. This is not morbid or inherent viciousness, as is proved by the fact that more than once a remarkably 'tough' gang has been enlisted, every member in useful work."

The best description of the formation and the

*From original research work made under the auspices of Columbia University, Department of Psychology, April 15, 1910.

political power of gangs is given by Robt. A. Woods in "The City Wilderness" (page 114), Chapter 6, entitled "The Roots of Political Power": "The importance of the 'gang' as a social factor which the politician manipulates has never been fully appreciated except by the politician. It is a sufficiently commonplace trait of human nature for people to associate themselves together in groups and cliques according to attractions of congeniality. The force, however, seems to work with great intensity in the tenement-house districts. Without pausing to inquire the reasons, I shall describe the structure of the gang, and later show its relation to ward politics. The tendency begins among children. Almost every boy in the tenement quarters is a member of a gang. There are certain characteristics in the make-up of all gangs. To begin with, every gang has a 'corner' where its members meet. This 'hang-out,' as it is sometimes called, may be in the center of a block, but still the gang speaks of it as the 'corner.' The size of the gang varies from 5 to 40. As a rule, all the boys belonging to it come from the immediate vicinity of the corner. Every gang has one or more leaders, for, as one of the boys expressed it, the leader says 'Come, and the push move.' As a matter of fact, if the gang is at all large, it has two or three leaders. In order to show the different kinds of leadership, let me describe the qualities possessed by different types in a large gang.

"First of all, there is the 'gang's bully.' He is the best 'scrapper' in the gang. Many a hard-won battle has paved the way to this enviable position, but the position, often obtained with some difficulty, is not a sinecure. The 'bully' not only has to defend his gang, but also his title against the ambition of some growing member of the gang. Next there is the 'gang's judge.' All matters of dispute are finally submitted to him. If no agreement is reached, the boy who has gained this honor has gained it, not by election, but by selection. The boys have gradually found out that he does not take sides, but is fair-minded. Finally, there is the 'gang's counsellor.' The boy whom the gang looks to for its schemes, both of pleasure and of mischief. In small gangs the 'bully' may be both 'bully' and 'counsellor.' Sometimes this happens in larger gangs—here is the 'Ward Boss' in embryo.

"Nightly the gang drifts to their corner, not by appointment, naturally. The ensue idle talk, 'jawing' matches, and rough jokes. Nearly every gang has 'talent,' one or two members that can sing, dance, perhaps a quartette or two buck dancers, a jewsharp, and a 'funny man.' I am referring to boys over 14. The songs are always new ones; old ones are scorned. Not infrequently the singing, the horse-play, or dancing is interrupted by the roundsman. At the sight of the brass buttons there is an excited call of 'cheese it,' the singing, etc., is suddenly stopped, the gang dissolves and flees down alleyways or to doorways, and curious hiding places and reappears only when the 'cop' is well down the street. It sometimes happens that members are arrested for standing on the corners, for insulting passers-by, or for other offenses. As a rule, the other fellows raise the money to pay the fine. To reimburse themselves or the one who loaned the money, a dance is run or a raffle is held. To show still further the tenaciousness of gang life, the influx of Jews has caused many of the Irish to move away from the South End, but the boys on Sunday may still be found with their gang at their 'corner.' Fully half are fellows who live at Highlands at the edge of Roxbury. I know a boy in High School—he will graduate next year—who moved to Dorchester, but comes regularly to the old 'corner' on Sunday afternoon. No new friends can supplant the old ones.

"It is interesting to know what becomes of the various gangs when they are a little older (17 or 18). The more respectable gangs club together and hire a room. The vicious prefer to use what little money they have on carousing. If by chance they get a room, their rowdyism will cause their ejection, either by the landlord or by the police. Consequently, they have to fall back on the corner or some saloon as their meeting place. They always try to seek a back street or wharves unfrequented by the police. Not infrequently these gang connections are tenacious in the case of older men, who sometimes meet in the back of some store to play 'forty-five,' but more often would be found in some saloon. In numerous cases a saloon serves as a club room for one or more of the gangs of these older men, who are loyally devoted to it. Many of them will walk by a saloon thirsty, in order to reach a particular drinking place with enough money to secure the proprietor's welcome.

"At this point it is necessary to give an account of the young men's clubs, in order that the important part that these clubs play in ward politics may be seen, for all this network of social life is taken in hand by the politician. As I said before, the gangs which coalesce and form these clubs are the most respectable ones. Such a club opens up the freedom of the district socially to them. Each gang composing it is likely to have a candidate for the principal offices and the first election is frequently a source of quarrel between the rival gangs which breaks up the club before it is properly started. There are about eight of these clubs in the particular section which I know best. The dues range from 25 cents to 50 cents per week, and the club usually pays from $25 to $35 per month for the room. Nearly all the clubs have a common program. In the first place, each club, without exception, gives a ball every winter. The tickets invariably sell for 50 cents. These balls are important social functions in the districts. As a rule, each club has a 'social' once a week. This is a dance of a lower type, being interspersed with comic and humorous songs, etc. About the same girls go from one social to another. * * * The worse dance halls are nearly allied to the clubs. This clientage is made up, though not distinctly, of gangs. Consequently, at nearly all the balls the dancers are known to one another, and have more or less loyalty for the hall. At one hall a large group of fellows attend, nearly all of whom have stylish light coats and dudish attire, even if they do not know where the next meal is coming from. In winter their mistresses support them. In summer these men go to Nantasket and to the beaches, and in the fall they take their gambling outfits to fairs at Brockton and elsewhere.

"The description thus far of the 'gang,' the social club, and the dance hall shows that the politician does not need to deal with the individuals. Ready at hand are these social centers for him to make use of."

And so the story goes on till ultimately we have corrupt political bosses and their allies.

The following essential factors of both groups must be considered in order to make a comparison:

1. Heredity. 2. Early life and education. 3. Environment. 4. Examination, physical and psychological.

Heredity.—A, Class of parent (stock); A, Family history neuroses, insanity, etc.; B, Drunkenness in parents; B, Age of death of parents.

The vast majority of Columbia freshmen come from good family stock. Poverty is no sign of real psychological caliber of the family. The mere fact that study is encouraged often at a great sacrifice is proof in itself of an ambition to reach a higher plane in life. Even if a student must "work" his own way through college he must support himself alone. Only in the rarest cases does the home make any demands on his income, and in such cases there is a surplus over the actual necessities of life, or the fees, cost of books, carfares, etc., could not be paid. If the money for the tuition, etc., is borrowed from a relative or a good friend, this benefactor must recognize a good reason for the loan; that is, either a certain responsibility on the part of the borrower and his family that it shall be repaid, or it is actually a gift. In the last case some reason for the gift must be appreciated, thus placing the individual on a scale above that of the average gang members.

In the case of gangs the rule is that the boy must become a wage earner as soon as possible, and were it not for the enforcement of the law, the majority would leave school long before they became of age. It is a surprising fact that many are either entirely illiterate or barely capable of reading, writing, and doing simple arithmetical sums.

If we inquire into the family history of the gangs we find in a large percentage (46) of the cases one of the parents is a drunkard. I have not the actual statistics, and, on account of liability to misstatements in order to hide the truth, the proportion of Columbia freshmen whose parents drink to excess can only be estimated, but it is fair to assume that it is rare to find a drunkard parent and almost impossible to find both parents thus afflicted. It is accepted that drunken parents cannot take care of a home and children as well as sober ones. A drunkard also is more liable to beget offsprings who are defective in one way or another. Among these may be mentioned epileptics, cardiopaths, mental defectives, sexual perverts, idiots, and criminals. Thus we have, excluding poverty at the outset, before birth, one cardinal cause for the differences.

In analogous ways we can compare parents who are criminals. Comparatively, it is rare to find a criminal parent of the freshmen, and how common it is to be found of the gang member. Reliable statistics could not be obtained, but one-half of those examined state that a near relative had been arrested.

In the history record it was noted that 17 had near relatives—brothers, sisters, parents, uncles, aunts, or first cousins—who had what seemed to be epilepsy. A history of insanity was given in five cases and four cases of mental deficiency in near relatives, and 18 had fathers who had "violent tempers," especially when drunk. Only one-half of the boys "really loved their parents." These figures are very different from what we knew we would find on examining the history of the Columbia freshman's family. In Paris, says Travis, 47 per cent. of the prisoners have indigent parents. Münsterberg, in "On the Witness Stand" (page 242), states, "When a school for criminal boys was carefully examined it was found that of 200 boys 127 were deficient in the direction of hysteric emotion, or in the direction of epileptic disturbance. In 85 one or both parents were drunkards, in 24 cases the parents were insane, in 26 epileptics, and in 20 others suffering from other nervous causes. Not the criminal tendency was born with the poor children, but the insufficient capacity and resistance of the central nervous system, and this was their inheritance from abnormal and degenerate parents."

One of the most important points to be considered is the age of marriage. Ellis, in "The Criminal," states that fathers under 20 beget especially weak children, and from 25 to 40 beget the strongest. Many of those examined were married and state that their parents married young also. I could not ascertain the ages in all cases at which the parents married on account of the ignorance of the subjects, but the average of 83 cases stated the marriage age of the mother was 19.9 years and of the father was 21.15 years; quite a contrast to the freshmen, whose mothers' average age of marriage was 22½ years and the fathers' 27½ years; hence the degenerate offspring with criminal tendencies in so many cases. Ellis states that over 90 per cent. of criminals can trace some defect in near relatives. The exact percentage was not sought in either of the groups examined. It is a simple matter to obtain answers to such questions from prisoners, but exceedingly difficult from persons at liberty.

As a summary to the question of heredity, it must be recognized that the average freshman has much in his favor.

Environment and Early Education.—Closely allied to heredity in modifying a person's life is environment. It has often been disputed which is the more important. The "big brother" movement of the Probation Associations of the Children's Courts has as its foundation the importance of environment, the idea being that a total stranger to the prisoner who promises to take an interest in the boy or girl as a "friend" or "big brother" will seek to furnish the aid which is either missing or not properly given at home. Many children have thus been set on the path of honesty and decency.

The writer has helped many children in this way and personally knows of a large number of others who have been similarly assisted. This plan is in vogue in some form wherever there are Children's Courts. As a rule, too much is expected of the "big brother" movement, and although many a boy may change from one "big brother" to another until the right man for the particular case in hand is found, many individuals are not at all amenable to the treatment. One case may serve as an example to show that environment is not always the most important factor to be noted.

A boy of 16 was sent to the writer, and after an interview with the family, for some reason, the family objected to the boy being influenced by the writer, and another "big brother" was found whom the boy and family liked very much. The parents are in comfortable circumstances and have four other children who have never been arrested. They do not live in a tenement district where gangs are most often established. This "big brother" gave the boy employment in his office and paid him a very good salary, so that money would be no object for the boy to steal. When the boy wished to go to the theater the "big brother" went with him. New associates were obtained by having the boy join a gymnasium far out of the neighborhood where the boy had his former playmates. Every evening

after work the boy was in the company of the "big brother," and the "big brother" made it his business to see that the boy reached home each night. This boy really loved his new chum. The habits of the boy became more cleanly; he acquired many essentials of etiquette and seemed to be entirely changed. After several months, a former friend, and now for some reason an arch-enemy of the boy, told the "big brother" of thefts the boy and his gang had been making while under the "big brother's" surveillance. Upon investigation, these proved to be true, and all the extraordinary efforts were in vain. The "gang" instinct still had the boy.

Since then the writer has again carefully inquired into the family history and finds that, although at the beginning it was given as "negative," it is now known that one near relative is insane, one epileptic, a brother a sexual pervert, a sister is a musical genius, and the mother is very neurasthenic. This case is one of the many which prove that environment is not by any means the *prime* factor causing the differences in the two groups considered.

The error lies too often in the examiner and the reason for such difference is not given. The fact that the vast majority of the fathers of Columbia freshmen are business men, either large or small, or are skilled laborers, is also at a variance with the second group. Of the cases examined only in one case was the father a grocer, and in two skilled carpenters; all the others, 97 per cent., had parents whose means of livelihood could be classed as unskilled; 14 had no work at all and 38 had no fathers, while 9 were orphans. Of 100 Columbia students questioned, the results were unskilled labor 3 per cent. (farmers), father dead 3 per cent., and mother dead 5 per cent.

The income of the parents of the students being higher, they are more able to give their children proportionate assistance. The appreciation of education of a class, almost all of whom belong to skilled laborers or higher, is naturally more than might be expected in the second group.

The parents, themselves, having had more education, having better means for procuring it, and knowing better its advantages in the struggles of life, surely encourage their children in this direction. The result of the schooling a freshman has had in comparison to that of "gang members" (most of whom can hardly read or write) causes differences in the choice of friends. The average freshman would hardly seek an illiterate as a confidant, while the gang member doesn't want a friend with "highfalutin" ideas.

Each trying his best to do as the rest of his class does, often at great sacrifices, the freshman broadens his mind and studies, and the gang member practices pool, cards, dice, pugilism, etc. Each tries to excel and win admiration of his companions; as a result, the savant is the ideal of the student and he does not know of the race-track tout, the prize-fighter, etc., who has won the foremost praise in the minds of members of the second class.

Less money means poorer homes. Poorer homes have less comforts and joys in them and naturally drive the occupants to the streets; here they meet their gangs. If it is inclement weather, a poolroom or a saloon will give good shelter. Here they mingle with the vile habitués of a cheap slum bar or den and acquire their lowly habits and desires. In the "Young Malefactor" (page 122) Travis says: "Poverty causes delinquency." The New York Juvenile Asylum reports that poverty often pushes a boy out of his home and initiates him into the offender's life. Paris reports over 47 per cent. of the children arrested were poverty-stricken. The Superintendent of the House of Refuge finds cold and hunger a frequent cause for theft. The 27th Annual Report of Elmira Reformatory states: "Poverty prevents a boy from learning a trade; his ragged clothes often bar him from employment." Jacob A. Riis, in "The Battle of the Slums," under the title of the "Genesis of the Gang," says: "Less than 15 per cent. come from good homes and only one in 66 had good company. The boys take to the street because the home has nothing to keep them there. To lock them up in the house would only make them hate it more. The gang follows the line of least resistance."

Therefore, to sum up, the environmental differences of the two groups may be mentioned as: (1) Home. (2) Poverty. (3) Poor guardianship of poorly trained parents. (4) The early death of one or both parents. (5) Occupation of the parents. (6) Immediate surroundings—as the cheap saloon, poolroom. (7) Poor education and illiteracy, thus cutting some of the pleasures of the better group from those which could otherwise be enjoyed by the second. (8) Association with people of a lower strata makes the individual ignorant of what takes place in the more cultured division of civilization; hence the lack of high ideals and aspiration for such culture. This makes the desire of education for one class and takes it away from the other.

Psychological and Physiological Examination.—On account of the differences in education of both classes and especially the large amount of illiteracy in these subjects, some of the regular university tests were omitted and others added to take their place. For example, it seems almost impossible to make the subjects appreciate exactly what was meant by "threshold of pain;" therefore, after trials with 14 subjects, the algometer tests were purposely omitted. In its place the time estimation tests were added. Satisfactory coordination of the subject could not be obtained in the association tests and they were also omitted.

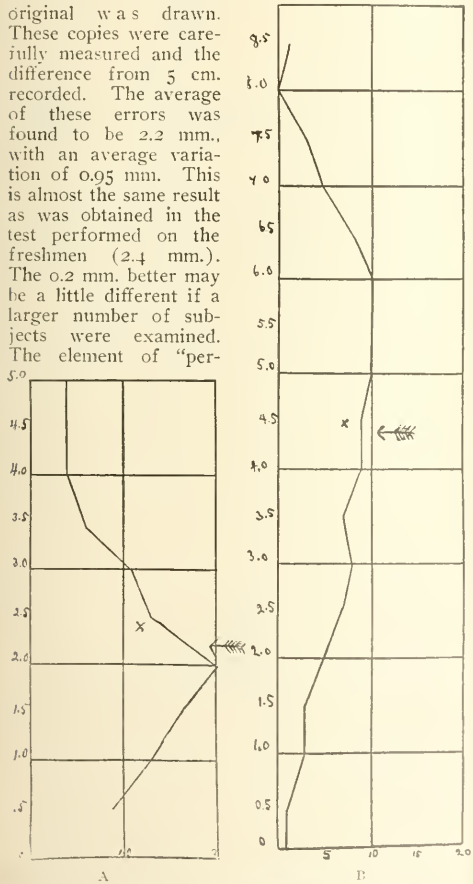
The following questions were asked at the outset of each examination: (1) Name? (2) Age? (3) Father alive? (4) Mother alive? (5) If father's dead, how old were you at his death? (6) If mother's dead, how old were you at her death? (7) At what age did father marry? (8) At what age did mother marry? (9) Father's business. (10) Does your father drink? (11) Does your mother drink? (12) Any near relative epileptic, insane, criminal, imbecile? (13) Are you married? (14) Tattooed? One or both arms? Other parts of body?

Tattoo marks are remnants of a barbaric custom. Explanations of these marks can be found in any book dealing with "degeneracy" or allied subjects. They occur frequently in criminal and other defective classes. For that reason I made it a point to investigate this matter in both these groups. I have never found a single student in the tank room of Columbia tattooed, except the fraternity men, who have their insignia tattooed over their heart or high up in the arm. This latter custom of college secret orders is compulsory, and can hardly be compared to the marks of individual egotism so extensively displayed. Of the one hundred gang members examined 14 per cent. were tattooed on the left arm; 8 per cent. on the right arm; 10 per cent. on both

arms, and 4 per cent. on other parts, a total of 36 per cent. The marks were usually nude figures, serpents, national flags, and initials.

After these questions were satisfactorily answered, the following tests were employed in the order given: (1) Estimation of size—5 cm. line. (2) Steadiness test—rod in a hole, 1 min. (3) Speed test—tapping, 100 taps and 1 min. (4) Accuracy test—rod in a hole, 1 min. (5) Strength of hand; (*a*) right, (*b*) left. (6) Tactile sensation—touch compasses. (7) Accuracy and speed test; (*a*) marking 100 A's, "A test," (*b*) dotting 100 squares, (*c*) dotting 100 dots. (8) mental imagery; (*a*) auditory, (*b*) visual. (9) Estimation of time, 1 min., ½ min. (10) Naming 100 colors. (11) Memory; (*a*) auditory for numerals, (*b*) visual for numerals, (*c*) retrospective for line 5 cm. (12) Eyesight. (13) Hearing.

Perception of Size.—This was the first test given. A line 5 cm. in length was shown to the subject and he was asked to reproduce it as nearly as possible. That the element of optical illusion might be avoided, the same size and kind of paper was used as that on which the original was drawn. These copies were carefully measured and the difference from 5 cm. recorded. The average of these errors was found to be 2.2 mm., with an average variation of 0.95 mm. This is almost the same result as was obtained in the test performed on the freshmen (2.4 mm.). The 0.2 mm. better may be a little different if a larger number of subjects were examined. The element of "personal equation" in the measurement also changes the result somewhat, but, on the whole, it may be said that in this test both subjects were equal.



A B

Fig. 1.—A is the curve showing the perception of size test. The vertical distance represents the number of millimeters that the line drawn by the subjects varied from 5 cm. and the horizontal distance represents the number of individuals tested. B is the retrospective memory test. The arrow indicates the average for gang members the cross the average for students.

The subjects were asked to remember the length of this line until all the other tests were completed, and then required to reproduce it again. This was the "retrospective memory" test. Measurements were made in the same way. The average error was 4.4 mm., with an average variation of 1.5 mm. The students showed an average error of 4.5 mm. Here again, if the small size of the groups and the matter of personal equation are taken into account, the results are quite similar. There was almost an hour's time between the first test and the "retrospective memory" test.

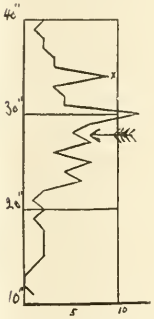


Fig. 2.—Curve showing the number of seconds required to make one hundred taps by one hundred gang members. The horizontal lines represent the number of gang members, the vertical distance the number of seconds. The average is indicated by an arrow for gang members and a cross for the students.

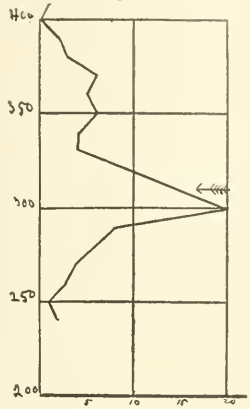

Fig. 3.—Curve showing the average number of taps made per minute by one hundred gang members. The horizontal distance represents the number of gang members and the vertical distance the number of taps. The average is marked with an arrow.

Steadiness.—For this test a brass rod 10 cm. in length and 3 mm. in diameter, attached to a wooden handle similar in construction to a screw-driver handle, was used. This brass rod was put into a series circuit with a battery and electrical counter and a brass plate. In the brass plate was a hole with a diameter 2 mm. more than the rod. The object was to stick the rod in the hole about 3 or 4 cm., without touching the side of the hole. Each time the side of the hole was touched, the circuit was closed, and the electrical counter registered an error. Special precautions were taken that the subject did not come in contact with the table or instruments with any part of his body except by the means already noted. The average errors for the "gang members" was 81.59 errors for 1 minute. They varied very much in this test, the best making only 9 errors and the worst 300.

Speed Tests.—The "tapping test" was used for this purpose. A rod, as was used for the steadiness test, but only 2 cm. in length, with the same handle as was used in the previous test and in a similar circuit, was used for the speed tests. The method was to touch the brass plate with the brass rod without touching the instrument or the table with any part of the body. Each time the current was closed the counter registered the contact. The object was to make as many contracts as possible for 1 minute. The time was taken when 100 taps were made. This averaged 29.9 seconds, with an average variation of

4.9. The average per minute was 322.1 taps, with an average variation of 29.4 taps. The students did not do so well; they required 34 seconds to make the hundred movements. The writer is unable to give any reasons for this difference.

The Three-Hole Tests.—The same apparatus as was used in the tapping and steadiness tests was used in the "three-hole test," and there was also used an equilateral triangle of brass with holes at each angle, about the same size as the hole or opening used in the steadiness test. The three holes were about 75 cm. apart and differed from the previous test in that the current was not closed unless the brass rod touched the bottom of the holes. The bottom was about 10 mm. below the surface of the brass, and the method was to take the brass rod (also used in the "steadiness test") and place it as quickly as possible in each of the three holes, without having the body touch the table or instrument. An electric counter registered when the rod touched the bottom of any of the holes, the requirement being to place the rod in as many holes as possible within a minute. The average per minute was 80.04 holes and the average variation 0.5 holes. This shows the inability of gang members to do accurate work quickly, as is also borne out by the other accuracy tests described hereafter.

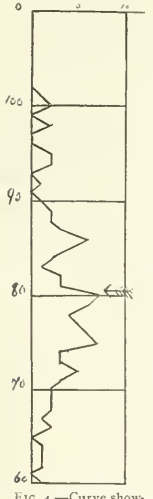

FIG. 4.—Curve showing the number of holes into which the gang members placed the rod per minute. The horizontal distance represents the number of individuals; the vertical, the number of holes. The average is indicated by an arrow.

Strength.—A dynamometer was used for this purpose. The arm was held away from the body and the subject asked to exert his full power. Three trials with each hand gave right hand 31.0 kg. as an average, with an average variation of 3.4 kg. This is decidedly less than the strength of the freshman who could press 36.3 kg. The left hand did not vary so much from the students, 32.5 kg. for the gang members and 33.5 kg. for the students. If we note that so many of the second group are left-handed, thus making the average for the right hand weaker and the average for the left hand stronger, part of the difference may be explained. It is an established fact that criminals and other degenerates cannot squeeze a dynamometer any better than normal persons, although popularly they are supposed to be stronger, and it is quite in keeping that a group of individuals who may be classed midway between the degenerate and the normal should have a strength showing between the two.

Sensation Areas.—These tests were made with two points of a pair of touch compasses, one centimeter apart, and also with one point of these compasses. Each hand was tested in the following manner: After describing exactly what was desired, the subject was asked to place the hand, first the right and then the left, on a table, and the back of the hand was touched with the two points, and he was then asked to say "one" or "two," according to how many points he felt. Each hand was tried in this order, 2, 2, 1, 1, 2, and the number of times that correct replies were given were noted.

Twenty-two per cent. made 4 or 5 correct replies for the right hand and 30 per cent. made 4 or 5 correct replies for the left hand. The students did very much better, 63 per cent. having made 4 or 5 correct replies. If we allow for the hardness of the skin of the hands from manual labor and the

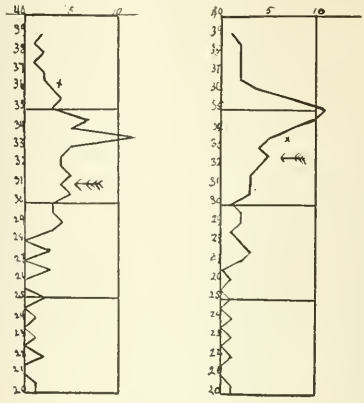

FIG. 5.—Curve showing the kilograms indicated on a dynamometer. The vertical distance shows the number of kilos., the horizontal the number of gang members. A is the right hand, B is the left. The average for gang members is indicated by an arrow and for students by a cross.

dirt, paint, etc., there is a question whether the college boys did so much better as these figures indicate. There is probably some difference, but it is quite difficult to state the amount exactly. The average of the 100 subjects was 2.7 times, with a variation of 0.9 for the right hand and 2.6 times, with a variation of 1.3, for the left hand.

Marking 100 Letters.—One hundred capital "As" are irregularly arranged among five hundred letters in printed lines. The subject was asked to place a dot over each "A" as quickly as possible. One point was to be given for speed and one for accuracy. The average time for going through the test was 115.4 seconds, with an average variation of 10.6 seconds. The average error was nine omissions, with an average variation of 6.9. The average time for the freshmen was 100 seconds. That the freshmen who read and write so much more should excel in a test in which they have had so much allied practice is to be expected. The figures for the errors of the freshmen are not given, but these also in all probability are much less for the same reason. Wisslar reported an average of only three omissions in a similar test given to forty-two Barnard students. The average time in the last was 91.4 seconds, due probably to the causes given.

Marking 100 Accurate Movements.—In accuracy tests the gang members are much inferior to the freshmen. Several tests were tried, some of which would hardly count for accuracy tests in the freshmen trials.

Dotting 100 Squares.—One hundred 1-cm. squares are arranged in rows of ten, thus making a large square 10 cm. by 10 cm. The subject, at a given signal, is required to place a dot as quickly as possible in each square without touching any line, and without putting more than one dot in a square or without leaving any square undotted. Each dot that touched a line, a square without a dot or each square with more than one dot was counted an

error. Credit was also given for speed. The subject was not permitted to touch the paper or table with any part of his body, except the hand holding the pencil. The average time for the contingent of "gang members" was 49.6 seconds and the average variation 11.0 seconds. The average error was

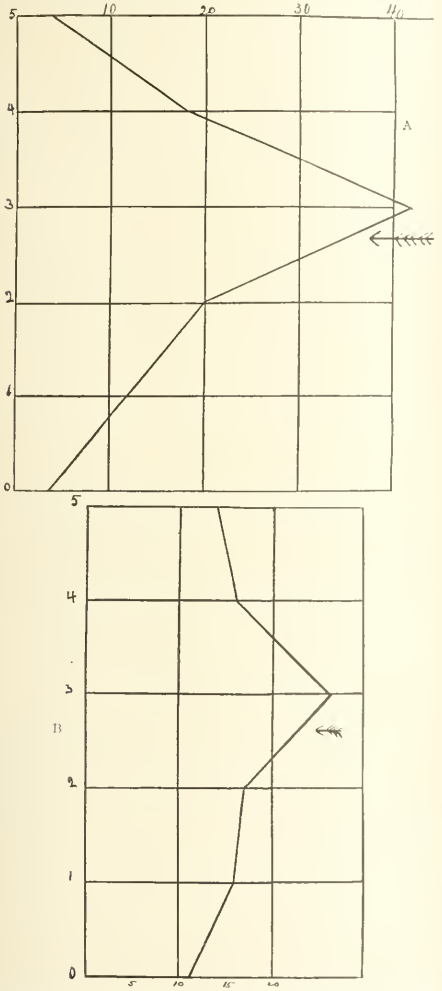

Fig. 6.—Curve showing the number of times one hundred gang members were correct with the touch compasses. The horizontal distance represents the number of subjects; the vertical, the times correct. The average is indicated by an arrow. A is the right hand, B is the left.

10.6 seconds and the average variation for the errors was 8.5 seconds, as contrasted with the average time for the students, *i. e.*, 34 seconds. The second accuracy test was very similar; this was dotting one hundred dots.

Dotting 100 Dots.—A 10-cm. square containing 100 dots 1 cm. apart were to be touched with a pencil at a given signal as quickly as possible, the same rules holding as in the previous test. Every dot not covered by a pencil dot was counted as an error and the distance the pencil dot was from the printed dot was measured. The average time for the students was 49 seconds, and the average error was 0.6 mm. The gang members took 54.04 seconds and the average variation of 9.3 seconds. The average error was 1.6 mm. and the average variation 6.3 mm. This, again, was very much worse than the students.

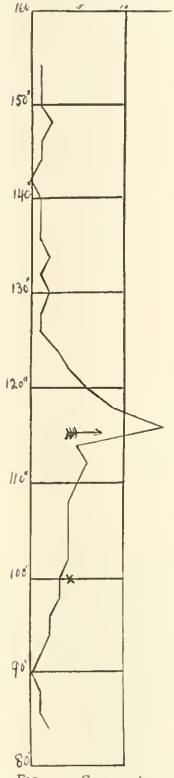

Fig. 7.—Curve showing the number of seconds required to mark one hundred capital "As." The vertical line shows the number of seconds, the horizontal the number of individuals. The average for gang members is indicated with an arrow, and by a cross for students.

Mental Imagery.—The "Imagery Blank" employed at the Columbia Psychological Laboratory was used, but only the following questions were asked, on account of the class of subjects examined, and even with these questions often an extended explanation had to be given: (1) Can you call to mind better the face or the voice of a friend?

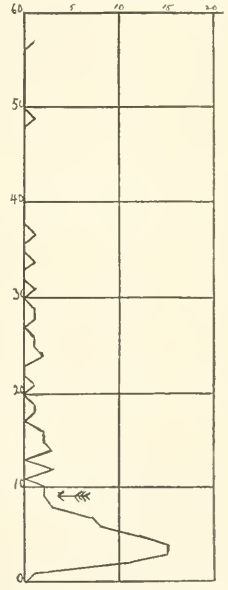

Fig. 8.—Curve showing the number of omissions made in dotting 100 As. The vertical distance represents the errors and the horizontal the number of individuals. The average is indicated by an arrow.

(2) When "violin" is suggested do you first think of the appearance of the instrument or the sound made when it is played?

Only two lists of answers were recorded; the first was called "imagery by visualization," that is, those who recognize a friend by his face or a violin by its shape. The second was called "auditory imagery"—recognizing a friend by his voice or violin by its sounds when it is played. The gang members averaged 54 per cent. for the visual and 46 per cent. for the auditory imagery. The average for the freshmen could not be obtained, but for the distinct visualization 83 per cent. is the figure given in contrast to 23 per cent. for auditory imagery distinct. Therefore it is likely that the two almost equal results of the gang members would be very much overbalanced by the visual imagery of the freshmen. Attention is again called to the fact as noted under "hearing" that gang members meet in

the dark, etc., and thus *live* more by their ears than by their eyes.

Perception of Time.—The subject was seated in a chair in a room with the examiner, and as far as possible no outside noises were permitted to distract attention from the work at hand. After resting a few moments the subject was told at the word "start" to begin to reckon a minute, and when he thought the minute was exactly over to say "now." The time was recorded with a stop-watch. After a few minutes' rest he was told to try to estimate one-half minute in the same way and begin at the word "start," and when finished to say "now." The time was recorded as estimation for one-half minute. The entire process was then repeated, thus giving two answers for the minute and two for the half-minute. The average result was remarkably accurate and at least disproved the notion that individuals who waste much time and are idle finally lose its exact mental measurement. In other words, it is often believed that idleness, irregular hours for meals, sleep, and work without feeling of responsibility to any one must eventually dull or paralyze this "time-thought" faculty from lack of use or practice. So it is with most of our mental phenomena. Perhaps it may be explained that subjects of this age have not wasted time long enough to cause such a dwarfing of this power; or perhaps students who are so frequently in a hurry and hampered for time getting away at top-notch speed, not to be late in the morning; eating as quickly as possible so that a half-hour can be spent in the library, on the athletic field or in consultation with a professor; at night finishing study in a hurry to get to dances, to make social calls, to attend students' meetings, etc., causes them to become hypersensitive from constant irritation in this particular. The conclusion seems to prove this fact, for the average time of 30 students for guessing 1 minute was 49 seconds, with an average variation of 6 seconds, much shorter than 60.8 seconds, with an average variation of 6.2 seconds, for the gang members.

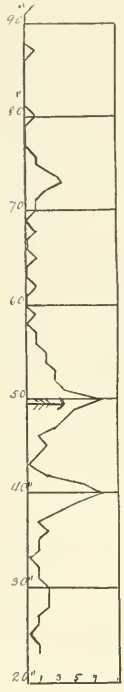

Fig. 9.—Curve showing the number of seconds required to dot one hundred squares. The vertical distance shows the number of seconds and the horizontal distance the number of subjects. The average is indicated by an arrow.

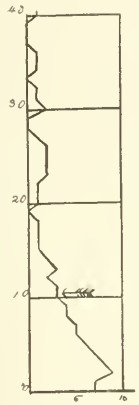

Fig. 10.—Curve showing the average number of squares that had more than one dot or a dot touching one of the sides of the squares. The vertical distance shows the number of such errors. The horizontal the number of individuals. The average is indicated by an arrow.

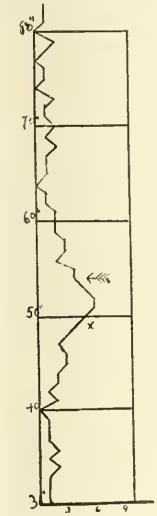

Fig. 11. — Curve showing the number of seconds required to dot 100 dots. The vertical distance represents the number of seconds, the horizontal shows the number of individuals. The average is indicated with an arrow for gang members and by a cross for students.

The most remarkable fact is that 19, or almost 10 per cent., estimated exactly 60 seconds, and 34, or 17 per cent., of the guesses were only 1 second out of the way. That is, 27 per cent., over one-fourth, were not more than 1 second wrong. In one-half-minute trials 30 students estimated 38 seconds, in contrast to the 100 "gang members," who averaged 28.5 seconds and had only 4.2 seconds as an average variation. Here, again, 33 exact guesses of 30 seconds were made, and 87 or 43.5 per cent. of the guesses did not vary more than one second from the exact 30 seconds.

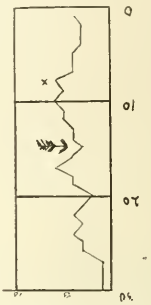

Fig. 12. — Curve showing the average number of seconds the subjects were away from the 100 dots. The vertical line represents the average number of mm. errors; the horizontal, the number of subjects. The average is indicated with an arrow for "gang members." Cross shows average for students.

Making 100 Colors.—A square piece of white cardboard on which were pasted 100 small colored squares, each separated by a square piece of the same size as the colored paper, arranged very much like a checkerboard, with colors of about the same intensity and arranged so that the two like colors would not follow each other—blue, yellow, green, red, and gray—was used for this purpose. The object was to begin at the top left-hand corner and name the colors as quickly as possible, reading from left to right on the first line, from right to left on the second, left to right on the third, etc., continuing in zigzag order, credit being given for speed. The average time was 80.49 seconds, with an average variation of 3.8 seconds, in contrast to the students, who took 85 seconds. Very likely the difference in eyesight had something to do with this difference, the total result being about the same as the other speed tests—somewhat in favor of the "gang members."

Memory Tests.—Just as important as accuracy tests are memory tests to distinguish the higher

mental faculties of various groups. As in accuracy, the memory tests show much better results for the freshmen than for the gang members. The following were the tests employed: Auditory memory, visual memory, retrospective memory.

Auditory Memory.—A printed set of numbers arranged in vertical columns of 4, 5, 6, 7, 8, and 9 digits in each column were used for this test. The same set of numbers were also used for making the freshmen tests. The object was to repeat the numbers as they are read, first 4, then 5, then 6, etc., until a point was reached where the numbers could not be remembered. If a slight error was made the test was tried with the second number in the column where such error occurred. If this happened again the third was tried, etc. The idea was to find out the *most* numbers that could be repeated perfectly. The average for the students in this test was 7.6 numbers remembered, while the gang members only remembered 5.9 numbers. The average variation for the gang members was 1.2, an average variation of more than 20 per cent. Practice in memory work, especially memory work as hearing instructors make explanations, somewhat similar to this test, is one of the main reasons for this difference.

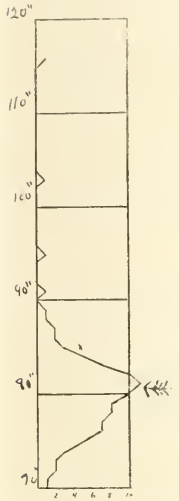

FIG. 14.—Curve showing the number of seconds required to name one hundred colors. The vertical distance represents the number of seconds, the horizontal the number of individuals. The average is indicated by an arrow for "gang members" and by a cross for students.

Visual Memory.—The objects used were three sets of white cards about the size of playing-cards. Each set had eight cards on which was printed in large black type digits about 25 mm. high. The numbers were shown at about the rate of three in two seconds, and when a set was completed the subject was asked to write down as many numbers as he remembered in the order they appeared. The three sets were always shown in the same order and each card in each separate set was shown in the same way at each test. Set No. 1 had the numbers 3, 9, 5, 2, 6, 8, 7, 4. Set No. 2 had the numbers 8, 5, 2, 7, 4, 6, 3, 1. Set No. 3 had the numbers 5, 1, 6, 2, 7, 3, 4, 8.

The results of the trials with the students were average correct, 6.9, almost one number less than in the previous test, auditory memory. The gang members had only 5.4 correct, with an average variation of 0.8, thus corresponding with the students, about one number less than in the auditory memory test. The numerals were so large and distinct that a small amount of "myopia" may be discarded.

Retrospective Test.—This was the last test and, as previously described, was to draw the 5-cm. line first shown from memory.

Vision.—In the vision test it seems that these "gangs" are a little better than the students. The reason is probably that eye disorders are more prevalent in the students from long-continued eye-strain. The result was for vision of the right eye, 72 cm. or over, 22 per cent. The college student only had 15 per cent.; 61.52 cm., 56 per cent., about the same in both groups; 44 cm. and under 22 per cent. The last is much less than the college student, in whom 33 per cent., or one-third, can see farther than 44 cm. This seems to be one argument in favor of the theory that myopia results from reading.

In *left eye* about the same result was noted: 72 cm. and over, 30 per cent., as contrasted with about one-half as many, 16 per cent. of the students; for the middle class, 61.52 cm., 60 per cent. in both groups, while only 10 per cent. could not see more than 44 cm. In the second group, 24 per cent., or nearly one-fourth, of the students were thus afflicted.

One of the most remarkable features of eyesight noted was that only 3 per cent. of 100 students had strabismus, while 24 per cent. of the gang members had it in the following proportions: Left eye only, 11 per cent.; right eye only, 9 per cent.; both eyes, 4 per cent. Some of the students may have had marked strabismus as children, but have had it corrected. The fact that this is one of recognized stigmata of degeneration and shows such difference in the two groups is quite important. In the same way it was found that 7 per cent. of the gang members were left-handed. This is also a recognized stigma showing the degenerate marks on gangs. It is generally accepted that from 2 to 4 per cent. of students are left-handed, about one-half the number that appear in gangs.

Hearing.—The hearing was tested with a watch which could be distinctly heard four feet from the subject (a regular dollar Ingersoll). If it could not be heard three feet from the subject the ear

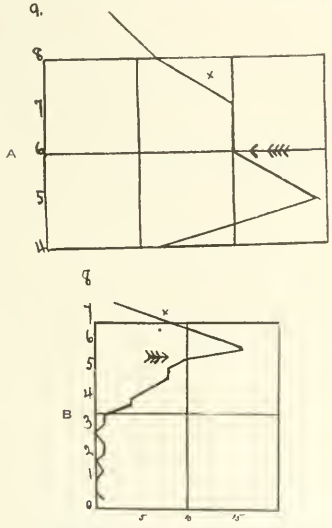

FIG. 15.—Curve showing the number of numerals heard and remembered. The vertical distance shows the number of numerals, the horizontal the number of subjects. The average is indicated by an arrow for gang members and by a cross for students. A indicates the numerals heard and remembered; B shows those seen and remembered.

was considered "abnormal." The students had 3 per cent. faulty hearing on the right side and 2 per cent. on the left, while four times the amount of the gang members were thus afflicted, 12 per cent. had abnormal right ears and 8 per cent. had abnormal left ears. If the constant use of eyes causes a weakness in them, and this fact is used as an explanation for the visual differences in these two groups, it is only fair to assume that those individuals who meet after dark hearken to footsteps of the policeman, pass a great deal of their time singing and telling jokes, in other words, live with their ears, have "near-hearedness," in contrast to the students who live with their eyes and have "myopia" or "near-sightedness."

Conclusions.—Although 100 is too small a number to make any sweeping statements, we are justified in noting the great variability in our subjects and the marked inferiority in accuracy, memory, hearing and tactile sensation in contrast to the Columbia freshmen. The "gangs" have in their favor only eyesight, speed, and estimation of time, and if a large number of subjects is taken different results may be obtained. When the finer faculties, as memory and accuracy, are taken into account, the students are by far superior. It is these qualities which make real class distinctions, and develop human endeavors in so marked a contrast to the rest of the animal kingdom.

In other words, the theoretical and practical results of heredity and environment are again demonstrated and the problem which presents itself to us is to assist the members of the "gangs" to the higher level of the freshman. This can be done only by removing the causes of the inferiority. The heredity cannot be altered, but the environment can and must be changed.

Jacob A. Riis, in the *Atlantic Monthly*, Vol. 84, page 301, writes: "The dangerous hours, when the 'gang' is made, are from 7 to 9, between supper and bedtime. This is the gap that the 'gang' fills out. * * * It is by the Boys' Club that the street is hardest hit. In the fight for the bad it is that which knocks out the gang and with its own weapon—the weapon of organization."

With such a purpose in view, Missions, Men's and Boys' Clubs, Y. M. C. Associations, etc., have been founded, the plan being to remove the boy from his evil surroundings which promote evil desires, which in turn so often father criminal tendencies. These places are made as attractive as possible so that the individual seeks them in preference to the street.

Experience and investigation of this problem prove beyond a doubt that many of the worst boys do not go to the club, and the few real vicious ones that do are not the most frequent callers. The same may be said of the Salvation Army, Volunteers of America, and other kindred church movements. As a rule, they claim that they save 50 per cent. or more of the cases they undertake. They, too, often overlook the fact that perhaps only 1 per cent. or even less of their members belong to the class which really would have become vicious without their generous assistance.

These numbers exclude discharged prisoners who may have reformed in prison and who would have remained so out of it without such organizations. So many boys who can neither be called members of a vicious gang or criminal are found in these clubs. They enjoy the attractions laid to catch the others. Here lies the fallacy of the statistics of these organizations, and their beneficence to mankind has been grossly overestimated.

The "Farm School" plan is a much better one. If a boy wishes he is taken from the city and placed on a farm after a course in elementary farming. The temptations of a big city are so far distant, the wholesome air, the good food, added to the removal of the friends to such a distance, offer a good way of changing the environment. The writer has known of at least four cases in which real vicious criminals have become honest, hard-working farmers. I would go even further and offer only one remedy to solve this problem. In every arrest where it is proved that the cause for the legal breach was due to "gang" environment, directly or indirectly, despite protestations of friends or relatives, an indeterminate sentence to the country should be enforced.

An attempt to run away from the farm is punished by a longer stay. After a time the prisoner will accuestom himself to the farm work and forget

the city, in which place his plans of life were incompatible. A city or State farm would not be nearly so desirable as one without the least semblance of a prison. Every farmer is anxious to get cheap help and positions are easily found; a free register could be arranged for such a purpose.

The benefits from such a plan socially and economically to such a country as this are almost beyond the limits of this essay to enumerate. (1) The congested districts would become somewhat relieved of overcrowding, especially of the immoral and evil spirits. (2) The farms would be better cultivated and the help cheaper. (3) The food supply would become greater and its cost less. (4) The succeeding generations would benefit by the improvement in the present one. (5) Many of the "workhouse" regulars would be taken care of, and the city relieved of their cost of maintenance.

This form of treatment is especially applicable to the juvenile delinquent. His character is more easily moulded and his health more quickly improved, as is shown by the report of Travis in the "Young Malefactor." On page 148 he states ("A Study in Juvenile Delinquency): "The maximum period of juvenile delinquency is from 14 to 16 years—the age of puberty. At this time not only the sex passions come into consciousness, but other impulses. The child is in general more susceptible, more nervous, and more easily influenced for good or bad than in any other period of life. One proof of this is to ask for a show of hands of those in a church audience converted at the age of 14 to 16. It is remarkable that 50 per cent. are converted at this period. At the Illinois Penitentiary 58 per cent. of the inmates committed their first offense before 25. At Elmira 89.9 per cent. of the inmates began their offenses before 20. In France 57.5 per cent. of those arrested are between 13 and 16. At Jamesbury, N. J., 60 per cent. are between 13 and 16; most are 15." Judge Lindsay claims that 20 per cent. of city boys are arrested. Cady, averaging all available data, concludes the average of the delinquent boy is 14.09 and the girl 14.71 years.

If only actual amount of work done on the farm would grant permission to return to the city, and then only if the prisoner works or he will be sent back, no such explanations for not working would be given as Speranza (page 163) found in 225 criminals under 25 years: Forty-eight said in essence, "We are good for nothing;" 25, "Our father does not work;" 22, "Work is fatiguing;" 14, "Begging is work;" 6, "Why work every day?" 10, "You make more by stealing;" 36, "We got along nicely by begging;" 8, "We haven't time to work;" 18, "Our employers discharged us; how can we work?" 19, "My father said only fools work."

Another proof of the value of this method of treatment can be realized if we note what Travis states in "A Study in Juvenile Delinquency" (page 132): "In the city life less track can be kept of the children, goods are more easily displayed and stealing becomes easier. Also playing in the city streets, the formation of gangs and their attendant phenomena of delinquency appear so clearly as to be formulated in the law that juvenile offenses spring up in direct proportion as the population increases. Less than 2 per cent. of delinquents come from the country, and 20 per cent. of the city boys between 10 and 16 years become offenders. Even when the centralization is temporary this law holds: Paris had twice the usual number of boys arrested during the exposition. At the St. Louis Fair girls were lured from their homes and there is suspicion that a certain society had raised $250,000 for supplying girls for immoral purposes."

TABLE SHOWING SUMMARY OF COMPARISONS

Name of Test		Average of 250 Students.	Average of 100 "Gang Members"	Average Variation of 100 "Gang Members."
Vision:				
Right Eye		15%		
72 cm. and over		15%	22%	
61 cm. to 52 cm.		52%	56%

THE METHOD OF SIMPLE EXTRACTION OF THE LENS.

By FRANCIS VALK, M.D., D.Sc.,

NEW YORK.

PROFESSOR OF DISEASES OF THE EYE, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

It seems to me that a paper on the extraction of cataract at present would be something like "carrying coal to Newcastle," as the subject has been written on and discussed for many years. But of late we have heard so much of the method of Major Smith's operation for the removal of the lens in its capsule that the time has come when the ophthalmic surgeons of this country should present their personal experience in this most important operation. From this personal testimony we may decide what method has been most successful in their hands; what have been their final results as regards the acuity of vision after the operation, and what have been the many complications arising during the various steps of the operation. On this subject we have had few papers and methods of operation, except those referring to the work of Smith of India and of the few who have attempted to follow that method in this country. I say this country, as, so far as my information extends, the method of removing the lens in the capsule has not met with a very cordial reception in England or the Continent.

Now as this subject has been presented to us so fully by Green, Wurdeman and others, in what seems to me a very favorable light, a just criticism of the method may not be out of place at this time. As I understand it, we have had very minute instructions as to the extraction of the lens in which, it seems to me, the assistant plays the most important part, and secondarily that the lens must be made to turn on its horizontal axis, so that the lower part of the lens may first present at the section, when we rupture the zonula by the pressure on the lower part of the cornea by the strabismus hook. Clark calls these cases, in which the lens turns, the intumescent (tumbler) cases. But does the lens perform the revolution? It may in some cases, yet, as I understand it, the lens fails to perform this step and is simply pressed out of the section by the direct pressure of the hook placed on the lower part of the cornea. I have been informed and seen it stated that the lens fails to make the turn in more than 75 per cent. of the operations. If this be true, then we may say that the operation is simply the old and, in my opinion, the classical operation of simple extraction without the cystotomy, in other words, a large section of the cornea, a rupture of the zonula by pressure and the extraction of the lens in the capsule. Now, this is no doubt a new procedure in the technique of this operation and the serious question is forced upon us: Shall we attempt it in our private and hospital work? Personally I cannot answer the question, as I feel the full force of reading the excellent and interesting papers on this subject, and the time may come when I shall attempt it, as the statistics presented to us by others with the remarkable acuity of vision that is claimed and the absence of a possible secondary operation, seems very enticing; at the same time the reported loss of vitreous compel one to hold back his approval until we can more fully understand just how and what the method will do.

Now one cannot justly condemn any procedure unless he is fully conversant with it and has seen the operation performed, and I must plead ignorance to both of these conditions, as I have not seen the operation performed, and I am only conversant with it from the published articles and discussions I have had and read; so I cannot claim to have any fair opinion, either for or against, but my object in this paper may be said to ask the opinion of the profession as to their individual methods of operation for senile cataract and to place before you my own method of operation and the results of that method during the past few years. Many years ago, now more than thirty, when I first commenced my work in the field of ophthalmology at the Manhattan Eye and Ear Hospital under the service of the late Drs. C. R. Agnew and D. B. St. John Roosa, we had only one operation in vogue at that time, namely, the combined operation of extraction of the lens with an iridectomy, many times called the Von Graefe operation, simply because we used the Von Graefe knife. This was the method in almost universal use and the one that I was taught in those days. But we lost many eyes—about 6 to 8 per cent. —and in 1887 I devised a new method of removing the lens without an iridectomy, and after a number of successful operations I published a paper on the subject in the *New York Medical Journal,* read before the Pan-American Congress in 1893. But at that time the subject of the "Simple Extraction" was rapidly coming before the profession, and the excellent results of Hermann Knapp's operations and his paper before the Section of Ophthalmology of the American Medical Association in 1892 brought the simple extraction rapidly into vogue, and I discontinued my own method, as probably too complicated for general use, and myself performed the simple extraction as so well presented by Knapp.

During these years my records show forty-seven operations, performed with the aid of the iris retractor to draw back the iris towards its periphery, so as to gain the advantages of an iridectomy without the traumatism of the iris, and after the extraction of the lens the iris was replaced without a coloboma. But after this series of operations, though without a failure and with good acuity of vision in a large majority, I gave up the method for the much more simple one of the simple extraction, which at that time was meeting with the approval of many operators. Consequently I have seldom performed the combined operation, or that with iridectomy. My records show eight operations with iridectomy, and then not from choice but because the existing conditions compelled me to remove a portion of the iris membrane, due to a shallow anterior chamber or to cutting the iris at the time of making the section.

Therefore in presenting this paper I have had a twofold purpose—that is to say, I wish to present my own views of the Smith operation as I understand it from the various reports published in the past, though I candidly acknowledge I have never attempted the method; and also my own experience in the removal of the sclerosed lens for the restoration of the sight. One may ask the question: How many operations shall we perform before we can come before the profession with our statistics, as it has been said we should have at least one hundred operations before we can judge of the value of any procedure? But considering the enormous number of operations reported by Major Smith, by which the lens has taken two distinct routes in its exit from the lens fossa, I fear that my own few operations will have but small consideration; on the other hand, I am encouraged to present this work

from the fact that our writers in this country present much smaller numbers, and so I may claim your indulgence in presenting the statistics of my last seventy-five operations, and I trust that by so doing I may learn and know the experience of other operators in this country. As previously stated, when I first commenced my work on the eye we were taught only one method of the removal of the lens—the so-called Von Graefe method—but in which the late Dr. D. B. St. John Roosa used to say "all that was left of Von Graefe's method was the knife." And this was very true, and in the natural order of change many sound modifications have been introduced, but in giving us this knife we have the most useful instrument in the extraction of the lens. Now, this Von Graefe knife is the most important instrument in the hands of the surgeon, as it is the only instrument by which you can make a perfect section of the cornea, and one that will tend to heal very rapidly. During the last few years I have wandered from the usual method of operation, and propose in this paper to present my present method and my statistics in reference to the same, taking from my case books the last eighty-six operations. I have selected this number simply for comparison with the last report by Greene of the Smith operation.

As the aim and purpose of this paper has been to present to this Section my personal experience in the removal of the sclerosed lens of old age, I may state that during my work in the field of ophthalmology I have not followed any special beaten track, but have endeavored by personal experiments to improve the technique, and the final results as to the acuity of vision in this most important and interesting operation. In my early work I did not know of anything more pleasing and instructive than to watch Dr. Ch. R. Agnew operate for senile cataract. His confidence, technique and success commanded my admiration, and his teaching has always been of service to me. But the profession must move onward, Agnew has passed away, and though his operations were very beautiful, yet in those days our loss was 6 to 8 per cent. At that time, also, every surgeon in nearly all cases performed the combined operation, that is to say, the iridectomy with extraction. Now these, practically, two operations performed at the same time on an eye which can hardly be considered a perfectly healthy one were possibly the cause of the high percentage of loss. So I left the old method and devised the Iris Retractor, as before stated, with which I drew back the iris and so made the exit of the lens very easy without the formation of a coloboma of the iris. (*New York Medical Journal*, Oct. 28, 1893.) Following up this method I have the records of fifty operations without the loss of a single case by suppuration. But I noticed that my cases did have a tendency to iritis more frequently than I wished. After this series of operations had been performed I had several in which the lens came out very easily without the use of the retractor, and my attention was drawn to the study of the simple extraction. At that time Herman Knapp was advocating the simple extraction with what he called a peripheral capsulotomy, but though I liked that method of opening the capsule I did not follow his suggestions in reference to the section, but did follow a method which to-day does not bear the *name of any author*, nor do I know when I conceived the idea of making the section as I do now. At the meeting of the Section on Ophthalmology in 1907, Weeks of New York read an historical paper on the "Incision for the Extraction of Cataract," and in which we find an illustration of the shoulder incision, and the statement that "the shoulder thus formed gives better support to the flap and a subsequent good healing with slight danger of prolapse of the iris is assured." This is the nearest explanation of the incision as I make it, but it is not the same as I will describe it. Let me say at first that, while I do not claim the incision as original with myself, yet I am unable to find any mention of it in the books at my inspection, yet I consider it one of the best, and one that is adapted to the most rapid healing. I will not dictate the preliminary preparation of the patient, nor of the eyes, as that is too well known to all my hearers, except as far as I never use atropine *before* the operation. Now—as to the section, I use a large and rather long Graefe knife, and make the puncture and counter-puncture about in the horizontal meridian of the cornea so that the upper or cutting edge of the knife will just clear the superior edge of the pupil. The *point* of the knife is then carried rapidly forward and upward, so that one side of the section of the cornea is made by one clean and smooth cut: the knife is now drawn backward and the heel of the blade carried upward, cutting the other side of the section clean and smooth. The cutting edge of the knife has now reached the superior edge of the cornea, and I now turn the knife on its long axis about one-fourth of a circle, and with one clean cut the section is completed wholly within the corneal border. In this way we completely avoid the to and fro movement of the knife, which would give us an irregular cut surface. Our next step is the opening of the capsule, and for some years I did the operation which Herman Knapp called the peripheral capsulotomy, by which the capsule was divided "from the nasal to the temporal side" behind the iris, near its periphery and parallel to the corneal section. This method I was very much pleased with. But I wanted to carry the section of the capsule all around—in other words, I wanted to make a complete peripheral capsulotomy. This, however, could not be done with the instrument then in use, as the cutting edge of the small knife would injure the pupillary edge of the iris, so I devised the cystotome, described in the *Ophthalmic Record*, August, 1900, page 382. This instrument is a single needle point set at right angles to the shank of the instrument. With this I found I could make a complete circle, with the cystotome carrying the needle point beneath the iris and about two or three millimeters beyond the pupillary edge—in other words, a complete peripherical capsulotomy. I have found no difficulty in making this large opening in the capsule, though in two cases it seemed as if the lens and capsule had moved somewhat as the needle point made its circuit under the pupillary edge. In all cases where this cystotome was used the lens made a rapid and clean exit. If this procedure does separate the center of the anterior capsule of the lens, it should tend to diminish the necessity for the many discissions now performed. Lang of London tells me he performs a discission in all cases without regard to the acuity of vision, but with this method of capsulotomy my statistics show that a secondary operation is very seldom needed. My next step is the removal of the lens, and this also is one of the most important steps, as I do not like the stroking of the corneal surface with the spoon, but placing one small spoon at the upper edge of the section, the other spoon is placed on the lower part of the cornea, and without being moved

from that position, steady pressure is made directly downward in the direction of the center of the eyeball. By this procedure we see the upper edge of the lens slowly tipping toward the section, until it comes into the pupillary space, and then the lower spoon is carried forward to complete the expulsion. Any remnants of the cortex that may remain are gently pressed out by depressing the upper edge of the section with the small spoon and very slight pressure below. I do not approve of excessive attempts to remove these small portions, as I prefer to leave them, as I have seen many of them naturally absorb, and if they do interfere with the visual acuity, I prefer a discission to any forcible expulsion. The toilet of the wound simply consists of replacing the iris, should it fail to return to the anterior chamber after the expulsion of the lens. This is done with a small spatula, the eye is carefully washed with a solution of boracic acid or salt and the eye closed. Both eyes are bandaged for two or three days, and the operated eye is kept covered with the bandage for eight to ten days.

Since I gave up the use of the iris retractor I have the records of nearly one hundred cases of simple extraction and of eight combined operations. Leaving out the combined operations and three in which I met with some special complications either at the time of the operation or during the healing process, some of which are reported in this paper, I present sixty-eight operations by the simple method. Of these I report twenty-one operations in which I did the complete peripherical capsulotomy with the final results as noted in these tables.

Total number of operations by the method of simple extraction with shoulder incision and the partial and complete peripherical capsulotomy.

My first series comprises 47 operations with the shoulder incision and the partial peripherical capsulotomy: 5 cases, V—20/15, with glasses; 12 cases, V—20/20, with glasses; 9 cases, V—20/30, with glasses; 4 cases, V—20/40, with glasses; 3 cases, V—20/50, with glasses; 3 cases, V—20/70, with glasses; 4 cases, V—20/100, with glasses; 1 case, V—20/200, with glasses; 2 cases, V—good vision, not tested; 3 cases, no report; 1 case, V—0, failure.

Complications arising during the operation or afterward: Vitreous loss, 1 case; iridectomy necessary, 1 case; discission, 9 cases; incarceration of iris, 3 cases; prolapse of iris, 3 cases; hemorrhage in anterior chamber, 1 case; iritis, 1 case. Two cases gave a diabetic history at time of operation.

My second series of cases comprises 21 operations with the shoulder incision and the complete peripheral capsulotomy with the needle point capsulotome: 2 cases, V—20/15, with glasses; 3, V—20/20; 3, V—20/30; 6, V—20/40; 2, V—20/50; 3, V—20/70; 2, V—20/200. With the following complications: Prolapse, 2 cases; iritis, 1 case; discission, 3 cases; hemorrhage in anterior air chamber, 1 case, and 1 patient with a successful operation on both eyes was diabetic.

Operations performed during the time of the above *and not reported* in this series, but which presented some complications, and while they may reduce the percentage, yet they show the incidents that may occur in any series of cases:

No. 124. This man had very poor perception and restricted field before operation. After removal of the lens he could see objects.

No. 127. This man did well until the fifth day after the operation, when he struck the eye a hard blow in the morning, ending in prolapse of the iris which was cut off four days later. Good perception, but no final test.

No. 122. In this case the house surgeon put atropin in the eye some hours before operation. This dilated the pupil to an extreme extent, yet after the operation the pupil did not respond and remained fully dilated when the man was last seen. No report of vision.

No. 112. This man having lost the right eye from a previous extraction, I removed the eyeball and did a preliminary iridectomy on the left. Healing being prompt and clean, I proceeded to remove the lens. The operation was smooth, but three days after I had suppuration with total loss. As this man was in the hospital all the time, it is hard to understand the source of infection in this case.

No. 104. This woman had a smooth operation, but three days after when pulling the bed clothes, her hand slipped and struck the eye. This was followed by suppurative iritis, ending in complete closure of pupil. Her field was so poor, I did not attempt to open the pupillary space.

Conclusion.—This paper is therefore presented as my personal experience in the operation for the removal of senile cataract and as all my operations have not followed any special method, it may have some interest. We may then ask what is the result of this personal experience? I would state that it does not seem to me essential that an iridectomy should be considered as a part of the operation for senile cataract, unless some unforeseen condition arises during the operation, to render the formation of this coloboma of the iris necessary. We find this condition in those people who may contract the lids at the time of the section so as to push the iris against the edge of the knife and the iris must be cut to complete the section. I have also found the same condition in three cases of very shallow anterior chambers, in which we can seldom make the shoulder incision, as I have described it, without wounding the iris. I also think that this section of the cornea is an improvement on the old method of the to and fro movement of making the section. Both of the above considerations I note are included in the advantages of the Major Smith method. Furthermore, it seems to me that the complete peripheral capsulotomy has some points of interest, as if the anterior capsule is lacerated in a complete circle the center of the capsule must come out with the exit of the lens, and, if so, we must have less necessity for the secondary operation. While I have not been able to prove that the center of the capsule has come out during my last operations, yet, as far as my observations have extended, it seems to me that my cases have required less secondary operations than those of other operators, as I understand that secondary discission is generally required in about 60 per cent. by the usual operation. But all this remains to be proved by the experience and by the results of other operators. I have not dwelt on the after-treatment of my cases, as in all this work I have followed the excellent suggestions of others, and in case a discission was needed, I have always tried to follow the suggestions of Zeigler and made the triangular opening in the capsule, a procedure that I think is an excellent one, and an advance in the performance of this delicate operation.

Finally, I present this paper in the hope that my personal experience in this most important operation may be useful to others in the domain of operative surgery in ophthalmology, and close with the words of A. E. J. Lister at the Bombay Congress, 1909:

"I repeat, however, let us be careful before we accept any dicta by any ophthalmologist, however distinguished he may be, on this important subject, unless supported by a series of cases, by an account of the operations performed, especially a statement as to whether the capsule was left behind or not, and if iritis or iridocyclitis followed."

164 East Sixty-first Street.

DEATHS IN CHILD-BIRTH.

By FREDERICK S. CRUM, Ph.D.,

NEWARK, N. J.,

ASSISTANT STATICIAN THE PRUDENTIAL INS CO. OF AMERICA.

An accurate statement of the ratio of deaths in child-birth to the total number of confinements in the general population is difficult and perhaps impossible. The accurate statistics are limited to those found in hospital reports and the hospital statistics may differ considerably from those of practitioners in the general population. Hospital statistics, too, are practically limited to urban populations and the rural communities might show quite different returns.

During five years there were 7,598 confinements recorded in the In-door Department of the Society of the Lying-in Hospital of New York City. During the same period there were 337 deaths of mothers during confinement, or a fatality ratio of 4.4 per 1,000 of total confinements.

In the In-door Department of the Lying-in Hospital of Boston during a recent five-year period there were 60 deaths in child-birth out of a total of 3,546 confinements, or a fatality ratio of 16.9 per 1,000 of total confinements. In the Boston Hospital the experience for practically the same period has been nearly four times as bad as that recorded in the New York Hospital. In the Boston Hospital a considerable proportion of the cases are difficult ones and this is probably the main reason for the high ratio of fatal cases. On this point the following quotation from the report of the hospital, for the year 1907, is of interest. "Many of the cases received for treatment have been of especial difficulty, and it is getting to be more and more the practice to send to the Hospital patients who are in a precarious condition, and patients who have been treated unsuccessfully outside and whose recovery is despaired of."

DEATHS IN CHILD-BIRTH OF MARRIED WOMEN
New South Wales, 1893–1905.

Previous Issue.	Number of Confinements.	Deaths in Child-Birth.	Ratio of Deaths to every 1,000 Confinements.
0	98,531	810	8.2
1	79,173	358	4.5
2	64,115	349	5.4
3	51,759	292	5.6
4	43,385	287	6.9
5	33,069	225	6.8
6	26,263	195	7.4
7	20,245	178	8.8
8	14,610	160	11.0
9	10,027	93	9.3
10	6,499	63	9.7
11	3,764	48	12.8
12	1,992	35	17.6
13	988	10	10.1
14	488	7	14.3
15 and over	362	5	13.8
Not stated	1	2	
Total	453,262	3,117	6.9

In the absence of reliable data for this country, the statistics of Australia may be of some interest. There an effort is made to collect statistics on this subject in such detail as really to serve a useful purpose. In New South Wales such data have been registered and compiled for a period of thirteen years, 1893-1905. These are of special value because they indicate the varying fatality ratios, according to the number, if any, of the previous confinements. The foregoing table presents the summary of these statistics:

According to this table, "the risk of death at the first confinement is higher than at any subsequent one up to the eighth. It is least at the second, but not much higher at the third. A most important consideration, therefore, so far as the risk of child-birth is concerned, is the number, if any, of the woman's previous issue."

Another factor of great importance in any consideration of the risk of death in child-birth is the age of the mother. In Western Australia the statistics are given in detail and the following table will be of special interest:

DEATHS IN CHILD-BIRTH OF MARRIED WOMEN
Western Australia, 1903–07.

Age of Mothers.	Number of Confinements.	Deaths	Ratio of Deaths to every 1,000 Confinements.
Under 20	1,075	4	3.7
20–24	7,266	28	3.9
25–29	10,625	57	5.4
30–34	8,842	53	6.0
35–39	5,348	41	7.7
40–44	1,634	17	10.4
45–49	135	1	7.4
Age not known	6	1	....
Total	34,931	202	5.8

This table indicates that the risk of death steadily increases with the advancing age of the mother. In this table, however, no distinction is made of the previous number of confinements, which, as the New South Wales statistics show, is a factor of considerable importance. From the data for Western Australia it is possible to calculate the fatality ratios of first confinements by ages of the mothers and the facts are summarized in the following table:

DEATHS IN CHILD-BIRTH OF MARRIED WOMEN
(First Confinements.)
Western Australia, 1903–07.

Age of Mothers.	No. of First Confinements.	Deaths	Ratio of Deaths to every 1,000 Confinements
Under 20	910	4	4.4
20–24	3,576	20	5.6
25–29	3,015	20	6.6
30–34	1,319	14	10.6
35–39	427	5	11.7
40–44	76	1	13.2
45–49	2	..	....
Total	9,325	64	6.9

The average fatality ratio of first confinements is shown to have been 6.9 for all married women in Western Australia during the five years, 1903-'07, for which the information is available. The chances of death during confinement of mothers without previous issue increase steadily with advancing age and the ratio of deaths to 1,000 confinements varied from 4.4 for mothers under twenty to 13.2 for mothers of ages forty to forty-four.

While it is not possible to state what proportion of confinement cases in the United States, or in any State, or in any given city, are likely to prove fatal, it would seem to be reasonable to assume that the ratio for all married mothers would vary from 4 or 5 to 10 or 15 per 1,000 of all cases. The variation in the ratios would depend upon the average age of mothers and especially upon the pro-

portion of the total confinements which were first confinements. Taken one with another, it is probably not far from the truth to assert that from 5 to 10 confinements out of every 1,000 are fatal to the mothers in this country at the present time.

A SUPPURATIVE ADENITIS UNDER THE STERNOCLEIDOMASTOID MUSCLE TREATED WITH STREPTOCOCCUS VACCINE.

By F. OP. De BEECK, M.D.,

NEW YORK.

This is the first time I have had the occasion of employing streptococcus vaccine. The venture was crowned with a result that was as surprising as rapid and that induced me to relate my experience, glad of the opportunity of making, even to a small extent, a contribution to biological therapy. The simple history of the case will enable one to comprehend the curative value that I attribute to the vaccine better than the most learned dissertation.

It is as follows: Mrs. X., aged 30, had been afflicted for eight days with a tumor situated on the left side of the neck, the illness being preceded by a sore throat about March 6. I was called to see her on March 12. There was a large swelling on the left side of her neck which was painful to the touch, a restriction of maxillary motion, and a temperature of 39.8° C. (103.6° F.). The tumor was hard, the skin red, and there was no fluctuation. There were also a swelling of the sternocleidomastoid, dysphagia, and vomiting.

After having tried the usual remedies in vain, to bring about a resolution, I made an incision along the posterior border of the sternocleidomastoid and reached the abscess after having incised the deeper fascia. The abscess was drained. In a few days the cavity filled up, the temperature returned to normal and all swelling had disappeared. I considered the case cured. This was on March 23. On March 28 I was again summoned to my patient. The swelling had reappeared, the temperature was 40.2° C. (104.4° F.), the rigidity of the jawbones pronounced, and the vomiting not infrequent. The swelling extended to below the clavicle, the submaxillary, submental, and thyrohyoid glands were indurated and the posterior part of the neck the site of an erysipelas. This was the state of affairs, when I had recourse to the streptococcus vaccine. I made an injection of ten millions of the bacteria at 9 o'clock in the evening, when the temperature was 40.5° C. (104.9° F.). The patient passed a good night.

The following is a record of the temperatures: Monday, March 28—9 P.M., 40.5° C. (104.9° F.) (injection); 12 M., 39.8° C. (103.6° F.). Tuesday, March 29—8 A.M., 38.4° C. (101.1° F.); 11 A.M., 37.8° C. (100° F.); 5 P.M., 37.4° C. (99.3° F.); 8 P.M., 37.2° C. (99° F.). Wednesday, March 30—8 A.M., 36.8° C. (98.2° F.).

All of the symptoms improved rapidly, the erysipelatous vesicles dried up, the swelling of the neck disappeared, and the patient was again able to take nourishment; everything returned to the normal.

On March 30 I administered 30,000,000 and on April 2 I made a last injection of 40,000,000. These injections were not followed by any reaction.

On April 6 I was sent for in haste. During the night the patient had been seized with vomiting and a fever of 40.2° C. Again there was a marked swelling at the left of the neck, pain, dysphagia, etc. I diagnosed another abscess. I made an injection of 40,000,000 bacteria. It was 5 o'clock in the afternoon. The temperature on April 6, at 5 P.M. was 40.2° C. (104.4° F.) (injection); 8 P.M., 38.9° C. (102° F.); April 7, 8 A.M., 37.5° C. (99.5° F.); 12 M., 37.1° C. (98.8° F.); 7 P.M., 36.6° C. (97.9° F.).

Again the swelling, pain, difficulty in swallowing, and vomiting disappeared. I made another injection of 40,000,000 on April 9. This time I was again of the opinion that the patient had entirely recovered when, on April 15, in going to see her infant, suffering with the same trouble, I found the mother confined to her bed, having again a swollen neck, but with symptoms less pronounced, the temperature only being 38° C. (100.4° F.). I gave her another injection of 40,000,000 and the next day her condition had returned to normal. I have decided to continue these injections, for the present, every four or five days, for some time. Under the circumstances I am absolutely convinced that it was the vaccine that cured my patient. I may remark that between the different attacks of the disease the patient was quite well and did not complain of any other trouble, moreover, that the ailment reappeared about six days after the last injection.

The child, aged 5 years, also presented a suppurative adenitis, following a sore throat, with a temperature of 39.4° C. (103° F.). I made three injections of 5,000,000 each. At the end of six days the temperature was normal and the adenoplegmon underwent resolution.

350 West Fifty-sixth Street.

AINHUM COMPLICATING UNCINARIASIS AMERICANA IN AN AMERICAN WHITE GIRL.

By FRANK L. ESKRIDGE, M.D.,

ATLANTA, GA.

This case is considered worthy of report because of its being unique—certainly cases of this type infrequently come under the observation of the clinician of varied experience and largest clientele—and because of the rarity of the disease, ainhum, in this country.

The disease ainhum was first described by da Silvia Lima of Bahia, Brazil, in 1867. The observations made later by other writers are similar to the original ones made by this authority. Ainhum is distinctly a tropical disease of unknown etiology and heretofore reported in the negro race only. The disease is characterized by a painless amputation of one or more joints of one or more toes by a trophic process. This process is carried out by the formation of a slightly constricting band, or furrow, at the digitoplantar fold of either toe. This band or furrow becomes in time more pronounced, firmer, and more and more constricting, until the confined portion of the toe enlarges and loses its natural shape. Inflammation and subjective symptoms are markedly absent except in the infected cases. In those cases occasional pain is felt. The constricting band continues to narrow, tumefying the toe, until finally only a small pedicle remains, from which the toe usually sloughs off (unless surgically removed), leaving a smooth amputated surface. The amputated base heals nicely. When ulceration takes

place, as in this case, the ulcer assumes a resemblance of a necrotic ulcer with a distinct nauseous odor.

As advanced by Unna, the condition is a sclerodermic callosity, with ring formation, producing a stagnating necrosis. The tumefaction indicates a stagnation, resulting in degeneration, retraction, and finally disappearance of the phalanges. The disease sometimes covers a period of several years.

Case.—Patient Miss V. H., aged 12, American born, was first seen by me at my office, November 1909, having been brought from one of the mill sections by Miss Ethel Hill, a district nurse. Her skin presented a waxy appearance of a dirty, muddy hue—typical Florida complexion—accompanied by the lack-luster of the eyes.

Previous History.—She had had the usual diseases of childhood. In 1906 occasional chilly attacks appeared. During the intervals between attacks she was entirely free from trouble except the foot condition.

Family History.—Her mother and father are living; the mother has nephritis; the father has a suspicious history of syphilis and hook-worm. Four brothers and five sisters are all sickly. The patient is the youngest child.

Personal History.—There is a neurotic taint; the sleep is good; she still has chills, though not so pronounced; the appetite is fair; bowels are constipated; she becomes tired and has malaise in the afternoons; there is an insatiable thirst. At six months of age a bleb or blister was noticed to appear on the left foot just above the digitoplantar articulation of the second toe, which soon broke down, forming a constricting band around the second toe. This process continued over a period of several years, resulting in the complete loss of the second toe and involvement of the third. At this time the foot presents a complete loss of the two toes, with the fourth toe confined in a constriction, having lost its natural appearance and shape, as shown in the illustration, while the great toe presents a deep callous plantar ulcer. Inflammation extends to the arch of the foot.

Examination.—The weight is 62 pounds; height, 4 feet 3 inches; temperature, 98.4°; pulse, 100; respiration, 20; hemoglobin, 40 per cent.; red corpuscles, 2,700,000; white cells, 58,000. There is edema of the feet and legs; the lungs are negative; over the heart is heard an anemic murmur; the tongue is furred and coated.

Urine.—The specific gravity is 1.014; the reaction, acid; albumin, negative; sugar, negative; indican in abundance; microscopic examination, negative.

The stool shows the presence of hookworm eggs.

The patient was placed upon weekly doses of fifteen grains of thymol for six doses given at night after a day's fasting, followed by the administration of an ounce of magnesium sulphate the following morning. After the sixth dose the stools showed no signs of eggs. The patient's family refused surgical interference with the foot, so it was treated along antiseptic lines with marked improvement resulting. The ulcer has practically healed, and while spontaneous amputation of the fourth toe is expected, after its healing the patient will have good use of the foot, requiring, however, a special shoe.

This case is doubly of interest because of the nature of both diseases, and because of the appearance of ainhum in the Southern States and in an American white child.

Ainhum is frequently met with in negroes in Brazil, India, and Africa, and occasionally in the Southern States, but I have been unable to find a report of a case heretofore in the Caucasian race.

301-2-3 Century Building.

AN IMPROVED PHARYNGOSCOPE.

By AUGUST L. BECK, M.D.,

MAMARONECK, N. Y.

Efforts are continually being made in the direction of invention and improvement of appliances for diagnostic and therapeutic purposes in all branches of medicine and surgery, the results of which are varying, and although all are not at first entirely successful, improvements follow rapidly in their wake. Oftentimes excellent contrivances are set forth only to fall into oblivion simply because of being beyond the pecuniary means of the average physician. Economic laws, such as demand and supply and the costs of labor and material, too often unduly influence the success or failure of the particular device. With full knowledge of these facts, together with others which will be hereinafter mentioned, I have endeavored to produce an instrument meeting all requirements without sacrificing any useful quality or any of its simplicity. In fact, adaptability, simplicity, and economy have been my very aim.

That the pharyngoscope, for the first model of which we are indebted to Dr. Harold Hayes, is rapidly gaining recognition and being more universally employed, is now an assured fact. With increasing and more general use of the pharyngoscope recourse to employment of the instruments of the Killian and Jackson types will be less frequently necessary except for purposes of inspection of the more deeply situated air-passages. Instances where the use of a local anesthetic is necessary are exceedingly rare. Difficulties experienced in the use of the Hayes pharyngoscope suggested to me certain modifications and improvements aiming chiefly at simplicity, thereby materially facilitating the manipulation of the instrument and widening the scope of its usefulness. The suggestions were made to Mr. R. Wappler, the maker, who kindly consented to carry them out.

The modified instrument is smaller, having one tube for carrying wires to the lamp and one tube for the telescope. This constitutes practically the whole instrument. The telescope tube has a wider diameter or bore than any yet made. No handle

was attached for the reason that in a large number of patients its use as a tongue-depressor handle causes marked gagging, so much so that further attempts to examine the patient at that sitting meet

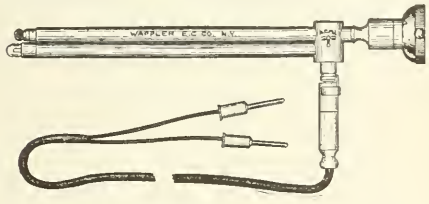

Fig. 1.

with very little if any success. Its absence enhances delicacy of manipulation and favors avoidance of contact with any of the sensitive parts of the mouth or pharynx. One great secret in its successful use is care in not touching any part of the anatomy of the posterior portion of the buccal cavity and pharynx, notably the soft palate and posterior portion of the tongue in the region of the circumvallate papillæ and lingual tonsil. Gagging is not frequent nor marked when the uvula is touched, providing these precautions have been observed. The posterior pharyngeal wall is also not often extremely sensitive. Sometimes a patient will in closing the lips around the instrument bring the soft palate and dorsum of the tongue in contact with resulting gagging. In such cases permit the patient to leave the lips parted with all the muscular structures relaxed. Care must be exercised in the manner of inserting the instrument into the mouth. A good way is to place the lamp extremity on the anterior part of the tongue at the same time resting the barrels or tubes upon the lower incisor teeth, the mouth being moderately open, then gradually pushing it backward along the dorsum of the tongue until the extremity reaches a point from ⅛ to ¼ of an inch from the posterior pharyngeal wall. The parts are then ready for inspection, the small ball on the eyepiece indicating the position of the lens at the distal extremity. In the majority of cases when the lens is directed upward an excellent view of the nasopharyngeal vault, nasal choanæ, and both Eustachian tube orifices may be obtained, as well as any abnormal conditions present. In many cases a better view of the orifices of the tubes may be obtained by rotating the lens from 20 to 45 degrees to either side of the perpendicular.

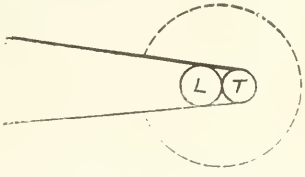

Fig. 2.—L, lamp; T, telescope; dotted line shows arc that can be examined without disturbing the position of the instrument. Is accomplished by rotating the telescope tube only.

This instrument having only one lamp gives a brightly illuminated and unobstructed view of one entire side of the pharynx without the necessity of rotating the whole instrument, as shown in the diagram:

On the other hand, the absence of a handle permits of rotating or reversing the entire instrument so that a view of the opposite side may be obtained in a similar manner. However, I have found that it is better to withdraw the instrument and reinsert it in the manner already described with the tubes in the opposite relationship to each other. By so doing the possibility of gagging is avoided.

Although the telescope itself is a comparatively large one, thereby exposing to view a large area, the diameter of each of the two tubes is approximately only ¼ of an inch. This makes the width of the intraoral portion ½ an inch, the actual combined width of both tubes. The importance of this reduction in size of the instrument as a whole is readily appreciated in examining children, and especially so in patients with greatly enlarged tonsils. This also applies to a similar condition in adults and in cases with peritonsillar abscess. It should be remembered that it is not necessary that the patient close the lips over the instrument, as this act is very often not conducive to perfect relaxation of all the muscular structures. This relaxation of the muscles of the pharynx is best obtained by allowing a distance of from ½ to 1 inch to intervene between the upper and lower incisor teeth aiming to have the mandibular joint as free as possible from muscular restraint. At the same time have the tongue lie passively on the floor of the mouth with its tip resting against the inner or posterior sides of the lower incisor teeth. The patient is then told to breathe quietly through both nose and mouth, thus overcoming the tendency for contraction of the muscles of the soft palate and favoring relaxation of same. In this way I have made perfect examinations. Dribbling of saliva is sometimes annoying to the patient, but does not interfere with the examination. Regarding the trouble encountered from condensation of moisture, I wish to point out that the clouding of the lens system during expiratory puffs does not occur at the distal or intraoral end of the telescope but upon the eye-piece or proximal end. This may be obviated by adjusting a pasteboard or mica shield at the proximal extremity of the instrument, which will at the same time protect the examiner from the breath of the patient. This has already been suggested by Dr. Hayes. Any distortion of the images of the parts under examination is due to malposition of the instrument and is easily corrected by remedying this. As with the old method where mirrors and reflected light are used, somewhat more difficulty will be experienced in cases where there is a large, thick, muscular tongue. A tongue depressor placed on or near the base of the tongue causes gagging and when placed more anteriorly causes crowding downward and backward of the structures near the base, thus interfering materially with sufficient elevation of the epiglottis. In this way marked obstruction is produced.

It is not the purpose of this article to cite cases examined and conditions seen by means of the pharyngoscope, but simply to enumerate some of the difficulties which attended its employment in my hands and to point out the advantages of the new instrument. For diagnostic purposes alone the pharyngoscope offers the simplest and easiest method of making examinations of the upper air passages. Improvements in the direction of invention of attachments for making topical application and also to the invention of instruments that can be employed with the pharyngoscope in position will probably suggest themselves as time goes on. It should be borne in mind that the smaller and simpler the instrument the easier will be its manipulation and the less disagreeable to the patient.

PSYCHIC GASTRIC JUICE IN MAN.

It is occasionally objected that Pavloff's discoveries concerning the gastric and other digestive secretions in dogs, which may be demonstrated at will on his animals with permanent fistulæ, need not apply to man, whose physical development is so far in advance of that of quadrupeds, however much agreement there may be in other than the psychic factors of digestion. It is conceded, we believe, that such uniformity as may be demonstrated in this respect among dogs is not to be expected in man. Fistula findings in the latter are but seldom procurable and the subjects are seldom healthy. It is doubtful if a treatise on stomachic digestion could be built up from such findings. Even Beaumont, so lauded as a physiologist, must be judged rather as a pioneer in experiment, as a man capable of recognizing an opportunity to be improved, and as a tenacious observer who followed up his advantages, than for his discoveries, which held good only for his particular subject and led to a vast amount of erroneous teaching, such as that all digestion was accomplished in the stomach, that the gastric secretion was produced by mechanical irritation by the food, and that the acid present united chemically with the food to form salts.

Hertz and Sterling have recently had an opportunity for the study of psychic gastric juice in a gastrostomy patient (*Deutsche medizinische Wochenschrift*, August 4, 1910). This subject had an esophageal stricture from swallowing concentrated lye. This was progressive and after three years a gastrostomy was performed. The stricture was treated, and the patient nourished by both routes. Recently he had masticated his food and introduced the pulp into the gastric fistula. At the time of the experiments the latter had been in existence seven years. Five years after the accident (hence two years after the gastrostomy) he went through a severe attack of empyema, which necessitated a resection of some ribs. The cause of the patient's coming to his present consultation was a second attack of empyema. It was after his convalescence from the latter that the experiments were undertaken. These were as far as possible parallel with those of Pavloff on dogs.

The few chemical substances which when introduced into dogs' stomachs cause a flow of chemical gastric juice so-called had no such action on this man's stomach. Nor did mastication of sapid substances cause the flow of an "appetite juice." Furthermore, there was not the intimate correlation in the simultaneous presence of appetite and a flow of gastric juice. Apparently either might exist without the other. The authors are far from attacking Pavloff's findings or conclusions. They believe that there is some looseness in the use of the word "appetite," and that better definitions are needed. They refuse to generalize from their findings in an isolated subject. Most of our readers will doubtless continue their belief in Pavloff's demonstrable teachings as underlying our general knowledge of digestion, however much these may seem to be contradicted by individual findings in mankind. Pavloff's teachings as to psychic gastric juice harmonize fairly well with what we know empirically of digestion and appetite in the healthy. At the time of their publication it was repeatedly claimed that they were not only not new to savants, but that laymen, even when untaught, were partly conversant with them. If anything these teachings were adopted too readily, and have served as a bulwark for numerous dietetic specialists, both medical and lay. If they are ever disproved it will hardly be through the agency of isolated experiments in human fistula subjects.

CARDIAC NEUROSES VS. CONDITIONS SUGGESTING GRAVES'S DISEASE.

Within recent years there has been gradually evolved the conception of a group of ailments presenting one or more of the familiar symptoms of exophthalmic goiter, in which, however, on account of the incompleteness of the clinical picture, the diagnosis of the latter condition is not permissible. To this group of cases Stern has lately applied the term *"Basedowoid."* As a clinical entity this has many features in common with the cardiac neuroses, from which in most instances differentiation has been impossible. Both are the result of an inherited degenerative tendency, and, developing gradually, are first rendered manifest by severe bodily or mental stresses. Of the many subjective symptoms that are identical in both groups, cardiac palpitation is the most prominent; next in frequency come dyspnea and a sense of oppression in the chest. Both conditions present many psychic manifestations, such as hyperexcitability, anxiety, impatience, hypochondria, insomnia, a sense of weakness, *globus hystericus*, dizziness, and a general mental depression. Occasionally there are fainting spells and sometimes the patient complains of indefinite pains in various parts of the body. Objectively both groups have the same clinical picture; there are the general stigmata of degeneration, increased cutaneous vasomotor excitability to mechanical and psychical stimuli, and seborrhea, loss of hair, hyperidrosis, salivation, and extensive dental caries. The tendon reflexes are increased, while those of the mucous membranes are diminished. The facial phenomenon and tremor of the lids and of the outstretched fingers are found in both groups of cases. Either the heart is normal or its action is exaggerated, with an indistinct first sound. Most of these

symptoms, including cardiac palpitation and respiratory difficulties, are manifestations of an increased excitability of the automatic nervous centers, while the remaining symptoms, including tremor and increased tendon reflexes, are attributed to an augmented activity of the sympathetic system. *Basedowoid* alone has a thyreogenous component which in some cases is sufficient to enable one to differentiate this condition by virtue of the presence of exophthalmos or of a struma that may be almost imperceptible.

Such being the similarity of the symptoms presented by both groups of cases, the discovery of a method that would enable one to determine to which group any particular case belongs would be a valuable addition to our diagnostic resources. Success in this direction has apparently crowned the efforts of Bernhard Aschner, who reports his interesting results in the *Zeitschrift für klinische Medizin,* Vol. 70, Nos. 5 and 6. His method consists in the subcutaneous injection of ¼ to ½ mg. of adrenalin. In cases of *Basedowoid* this is followed by an acceleration of the pulse, cardiac palpitation, dilatation of the pupils, pallor, trembling, nausea, a rise of temperature of from 0.5° to 1° C., a sensation of dryness in the mouth, slight headache, dizziness and, within two or three hours, the appearance of glycosuria. None of these manifestations occurs after the injection of a similar dose of adrenalin in normal individuals or in those presenting cardiac neuroses. The simplicity of this method and its ease of application particularly commend it in the diagnosis of cases frequently encountered in general practice.

TUBERCULOSIS AND POVERTY.

The question of tuberculosis has once again been threshed out in a fairly thorough way at the recent conference on the disease held in Edinburgh. Of course, in the discussion the mode of infection was very much to the fore and eminent authorities from different parts of the world retraversed that now well-worn ground. Perhaps the general attitude of the meeting was expressed by Prof. Sims Woodhead when he stated that in his opinion the infection was most frequently introduced through the air-passages, but that the alimentary canal was sometimes infected. Woodhead, however, strongly deprecated the tendency so often evinced nowadays of jumping at conclusions from insufficient premises. He said that caution was necessary in drawing conclusions from experiments, especially with the smaller animals, to determine the question of the avenues of infection in tuberculosis, for most of the experimental animals were mouth breathers. A paper was presented by Professor Bartel, of Vienna, in which he said that the chief result of recent investigations was that we had to admit our ignorance. Immunization experiments had demonstrated the importance of predisposition and to prevent infection the body must be strengthened. Several speakers at the conference professed opposite views as to the avenues of infection. Dr. T. Shennan of Edinburgh gave details of 1,085 post-mortem examinations in the Edinburgh Royal Hospital for Sick Children, and stated that 38.8 per cent. had died from tuberculosis and 82.0 per cent. of these had their lymphatic glands affected. He thought that much of this was due to bovine infection by the agency of milk. Drs. Fordyce and Dickson said that abdominal tuberculosis was very prevalent among children in Edinburgh and was due to infected milk. Thus, although no new facts were brought to light at the conference, the matter stands where it stood before, that the results of investigations and of clinical experience seem to show that the main avenue of tuberculous infection is by inhalation, but that a certain part of the infection originates in the abdominal regions and that many cases of infection of the lungs have come from the ingestion of infected food.

The most instructive portion of the discussion on tuberculosis in Edinburgh was that which dealt with the methods suggested for ridding the world of the disease, or, at any rate, for effectually scotching it. Now, it is obvious that poverty is a fertile, if not the most fertile, means of spreading and continuing consumption. As Dr. John McVail of Glasgow pointed out, it is a question whether phthisis is a cause of pauperism, or pauperism a cause of phthisis, and the answer broadly speaking is that phthisis causes pauperism in one generation and pauperism causes phthisis in the next. To a very large extent, then, tuberculosis is a workingman's question. In the first instance occupation is a potent cause of phthisis. There are some employments, such as steel filing, stone mason's work, labor in coal mines, the manufacture of some kinds of pottery, which in varying high degrees favor the contraction of the disease. Likewise, what is known as sweat-shop labor, undertaken under the most unsanitary conditions, so common in New York City and in other parts of this country, is a palpably frequent cause of its spread. But, indeed, little argument is needed to prove that workers of nearly every description are from the very nature of their callings rendered peculiarly open to the attacks of tuberculosis. Further, as a rule, their home life is against their recovery and very favorable to the dissemination of the disease. In the towns, too, often the workman's house is small, ill-ventilated, badly lighted, and overcrowded. The soil is particularly advantageous to the spread of the disease and the consequence is that if it does not sweep the district like wildfire it slowly and steadily makes its fateful way.

The successful treatment of every disease demands that it be attacked in its early stages. In consumption early treatment is absolutely essential to success. In the light of modern knowledge tuberculosis is, to all intents and purposes, always curable if it is dealt with promptly. The malady becomes less and less amenable to treatment with every day that passes until by the time that the patient is generally disabled hope of recovery has gone. But in the case of the working man, nine times out of ten, the application for medical aid is made too late. For many reasons which appear to him sound he does not want to leave his work, and, as Dr. Nathan Raw remarked at the Edinburgh Con-

ference, so far as the extinction of consumption is concerned the workingman and his wife are utterly hopeless. The problem would not be so serious were it not for the fact that the workingman suffering from tuberculosis in his overcrowded home in an overcrowded district is a menace to the community. If the disease went no further than the patient, it could be grappled with more or less easily, but when the sick man is a center from which infection is freely carried and finds favorable soil, the solving of the problem seems to present insuperable difficulties. Consumption will never be eradicated until practical methods are everywhere introduced of early diagnosis and of successful treatment of the disease among the poor. The first step toward this desirable consummation is the universal establishment in civilized countries of improved housing, improved workshops, and improved schools.

Some of the speakers at the Edinburgh meeting were in favor of the State taking up the matter of tuberculosis in the working classes, contending that the task is too formidable to be overcome by private enterprise. In any event, the conference will have served its end if it has succeeded in driving home the truth that in order to extinguish tuberculosis the disease must be attacked in its strongholds, the workshops and homes of the poor.

Lead Poisoning and Lung Affections from Working in Potteries.

Two reports have been issued in Great Britain dealing with the dangers to health attending those who work in pottery manufactories. The menace to health from this kind of employment is due to the use of lead compounds in making pottery, rendering the workers liable to lead poisoning, and to the injury to health arising from the inhalation of dust. The inhalation of dust of flint and clay is known as potter's rot. Dr. Russell reported that no less than 52 per cent. of potters over fifty showed signs of lung disease, and according to Dr. Shafflebotham bronchitis caused forty-four times more deaths among pottery workers than among the general population. The liability to and the contraction of plumbism is a far more serious matter among pottery workers than are the dust-caused diseases. The pottery processes in which lead is used employ in Great Britain about 7,000 workers, and of these 100 or thereabouts are attacked by lead poisoning every year. The evil, however, is much larger than the figures of cases indicate. Many cases of lead poisoning are concealed. In addition to the actual tabulated cases, the evidence tends to show that the general health of a considerable number of workers is impaired. Many of the pottery workers are girls and married women, and a grave consideration of the question is the effect of lead poisoning upon maternity. Thirty-one out of 121 mothers who were lead workers previous to marriage had miscarriages, and 21 out of 70 mothers who worked at lead processes after marriage were subject to miscarriages. Lead poisoning is a very insidious form of poisoning and in the large majority of cases exerts an injurious influence upon the worker. Of course, a tired or under-nourished worker is more prone to be poisoned than a healthy individual and for this reason it is essential that those who work in lead pottery manufactories should be as well nourished as possible. The British report recommends that employers should supply their employees, especially the delicate ones and the girls and women, with milk or milk and cocoa before they commence work and at intervals after. But Miss Gertrude Tuckwell, the only woman inspector who signed the report, makes a more sensible suggestion—that taking into consideration the fact that pottery can be made without lead glazing the use of lead should be prohibited in its manufacture. A British labor paper, commenting on the matter, makes the humane recommendation that lead-glazed pottery should be boycotted. It is now beginning to be widely recognized and appreciated that human life and health are of more value than the amassing of riches, and the time is not far distant when this wise principle will be acted on.

Trichinosis.

Though human infection with *Trichina spiralis* is a matter of deep concern to the sanitarians of various parts of Europe, the disease in this country is, as a rule, considered to be so rare as to attract very little attention from either clinicians or sanitarians. That this neglect of a disease so important and so serious as trichinosis is the cause of many mistaken diagnoses is emphasized by two articles appearing in the August number of *The American Journal of the Medical Sciences*. In one of these W. Gilman Thompson reports fifty-two sporadic cases seen by him in New York City during the past six years, and in the other Henry Albert reports a sharp epidemic which occurred among the students of Iowa College in 1907. Trichinosis is a disease easily overlooked by one not constantly on the watch for it, but diagnosed with the utmost ease by one keeping the condition in mind. Though often mistaken for typhoid fever such an error should be corrected in the course of a few days. The sudden onset with fairly rapid rise of temperature, the exquisite muscular tenderness, the peculiar form of diaphragmatic dyspnea, the slight puffiness of the eyelids and face, and edema of the ankles and possibly corneal hemorrhages, all associated with marked prostration, make up a symptom complex which should invariably suggest the presence of trichinosis. As soon as the possibility is suggested the difficulty is past, as the confirmation of the diagnosis is a matter of simplicity. The most positive proof of the infection is of course the finding of the *Trichina spiralis* in the muscle of the patient; the simplest is a differential count of the leucocytes. With a series of symptoms as above described the presence of over 15 per cent. of eosinophiles in the blood is practical proof of trichinosis, whereas a normal eosinophile content as distinctly excludes the disease. That Thompson in his own private and hospital practice has during the past six years seen fifty-two cases of trichinosis is probably not a matter of luck, but rather due to the fact that he has been constantly upon the watch for the disease and has recognized it when he has seen it. The comparative immunity which has been believed to exist in this country to trichina infection, owing to the fact that raw ham is but rarely eaten here, is shown by Albert to be a false security, for in his epidemic in Grinnel the ham eaten had been boiled. As this "boiling" process as carried on by the dealers consists in keeping the hams in vats for several hours, it would be expected that the parasites would be killed. On

investigation, however, it developed that the temperature was but rarely raised above 200° F. and in many cases did not exceed 170° F. Such "boiling" apparently does not render it a safe food and makes it of vital importance that all ham before it is eaten should be recooked in the house.

The Permanent Slow Pulse.

P. Rostaigne of Paris recently discussed the permanent slow pulse in an article published in the *Medical Press and Circular*, July 20. Adams, in 1827, was the first to describe the pathological permanent slow pulse and the question has come to the front again recently. As a rule the pulse rate in these cases is from thirty to forty pulsations a minute, but it is sometimes even slower than this. In a general way examination of the heart does not reveal anything abnormal in respect of the orifices, but Stokes, who, together with Adams, described the pathological condition known as Stokes-Adams' disease, called attention to a peculiarity of the heart that is sometimes met with. Between the audible heart contractions a dull, muffled sound is heard, which he regarded as an abortive systole represented only by auricular contraction. It follows that the heart sometimes splits up the systole into two parts, a superior auricular, and an inferior ventricular, which occasionally misses fire. Rostaigne shows that Stokes' observations are borne out by the present conception of the pathogenesis of permanent slow pulse. Permanent slow pulse is an affection that runs a long course. As a rule it lasts for several years, but the prognosis is always grave, indeed fatal. Since Charcot's time and up to a recent date, the Stokes-Adams' syndrome has been regarded as a consequence of disturbance of the circulation in the medulla, that is to say, the central nervous system was credited with a preponderating rôle in regulating the heart beat. In view, however, of recent physiological and anatomical researches, the myogenic theory has taken the place of the neurogenic, the conception of cardiac automatism is now generally admitted, and little or no importance is attached to the medulla as the seat of origin of the disturbance of cardiac rhythm. The symptoms observed in the course of permanent slow pulse are now referred to a lesion of His's bundle, and what is more important is the fact that syphilitic lesions have been found at the root of the mischief. As Rostaigne remarks, this is quite a novel conception and justifies our anticipating recovery, in many of these cases of permanent slow pulse, as a result of mercurial treatment.

Ophthalmic Migraine and Frontal Sinus Disease.

While sick headache, with or without such ophthalmic symptoms as scintillating scotoma and narrowing of the visual field, is as a rule an essentially neuropathic manifestation, cases are undoubtedly accumulating in which the eye manifestations may be shown to be due to organic disease in either the nasal fossæ or the sinuses; this is especially apparent when a condition like ophthalmic migraine, which has little tendency to spontaneous recovery, yields permanently to measures directed to the intranasal condition. Oertel of Düsseldorf reports in *Berliner klinische Wochenschrift*, of June 13, an interesting case in which a chronic catarrhal inflammation of the right frontal sinus caused increasingly repeated attacks of ophthalmic migraine. In this particular case there were no scotomata nor was there any retraction of the visual field; but there was marked asthenopia at the height of the migrainous attack. Various explanations have been advanced to account for such cases, and most of these deal with a reflex mechanism, although opinions differ as to how this becomes operative. Oertel inclines to Zarrikow's theory that accumulated secretions in the frontal sinus, or edematous saturation of the mucosa of the middle turbinate, or both conjoined, comprise the nerve endings, and thus determine the migrainous attack as a purely reflex phenomenon. In this type of cases drainage of the frontal sinus brings about a prompt recovery from the migraine. Both ophthalmologists and rhinologists seem inclined to accuse empyema rather than chronic catarrhal inflammation of the sinus, but experience shows that one condition may readily pass into the other and that nasal ophthalmic migraine need not necessarily suggest an empyema.

News of the Week.

Health of the Canal Zone.—In submitting the report of the sanitary department of the Isthmian Canal Commission for July, 1910, Dr. Gorgas points out that while the death rate among employees and among the total population is a little larger than for July of last year, it is still smaller than for any other preceding July. For employees the figures given are as follows:

Year.	Force.	Number of deaths.	Rate.
July, 1905	11,277	45	46.11
July, 1906	28,041	151	64.71
July, 1907	38,298	112	35.09
July, 1908	44,938	55	14.68
July, 1909	45,875	31	8.10
July, 1910	51,871	51	11.80

For the total population the figures for this and preceding Julys are:

Year.	Total population.	Number of deaths.	Rate.
July, 1905	41,084	237	69.22
July, 1906	74,777	422	67.72
July, 1907	103,333	357	41.48
July, 1908	121,607	295	29.11
July, 1909	135,871	207	18.29
July, 1910	153,186	287	22.48

Among the white employees there were 12 deaths, an annual average per thousand of 10.37; among the colored employees, 39 deaths, an annual average per thousand of 12.32. No cases of yellow fever, smallpox or plague originated on or were brought to the Isthmus during the month.

In Panama the inspection of buildings in reference to the harboring of rats has been completed, and it has been found that over 50 per cent. of the houses are suitable for harboring rats and possibly for their propagation. The city cannot, therefore, be considered in a satisfactory sanitary condition as regards a possible invasion by plague and plague-infected rats. Inspection has also been made of all roof gutters in the city which are breeding places for mosquitoes, since yellow fever is another disease which constantly threatens Panama. More than 50 per cent. were found to be in unsanitary condition, and persistent efforts will be made to have these changed as soon as possible. In addition to these inspections the usual routine work has been carried on.

Smallpox on Steamship.—A case of smallpox was discovered on the Atlantic liner *President Lincoln*, which arrived in New York on September 7. The steamship was detained at Quarantine until all the unvaccinated third cabin and steerage passengers were vaccinated. The patient was removed

to the hospital, and the occupants of the steerage compartment in which she had traveled were sent to Hoffman Island for observation.

Diphtheria in New York.—In the monthly bulletin of the New York State Department of Health a study is reported of the mortality in cases of diphtheria in New York. Attention is called to the larger mortality in New York City as compared to the State. The figures representing deaths per 100,000 of population:

	1908.	1909.
State of New York	28.9	27.5
City of New York	37.1	38.0

The conclusion is drawn that the mortality, which is excessive in both cases, is due to the neglect to make proper use of diphtheria antitoxin, a contention which is supported by the following comparison up to 1905:

	1902.	1903.	1904.	1905.
State of New York	37.7	39.2	38.4	28.4
City of New York	53.0	56.0	57.0	38.0
City of Paris	20.0	15.0	9.0	6.0

International Pure Milk League.—Under this title an organization was recently formed by a number of women in the City of New York at a meeting in the Hotel Astor. The league will devote itself to the investigation of the sources of milk supplies and the production of clean, pure milk at prices within the reach of persons of moderate means. In New York the league will cooperate with the Department of Health in any measures looking to the betterment of the milk supply.

Massachusetts' Oldest Man.—Patrick O'Hearne, said to be the oldest man in Massachusetts, died at his home in Worcester on September 8, aged 105 years.

Health Budget.—The Department of Health of New York City has made a request for an appropriation of $4,076,578 for the year 1911. This is $1,328,855 more than the department was granted for 1910. The principal increases asked for are as follows:

Division of the chief clerk	$48,949.50
Division of child hygiene	320,545.00
Division of contagious diseases	113,150.50
Division of general sanitary inspection	57,210.00
Division of milk inspection, city and country	60,510.00
Laboratories, research and vaccine	101,759.00
Division of hospitals	486,056.00

The Sale of the Ehrlich Preparation.—A dispatch to the New York *Times* of Sunday last gives an account of a meeting of American physicians in Berlin at which Dr. Marks, one of Ehrlich's assistants, announced that preparation 606 would be put on sale in this country in November. He said, as has already been stated in the MEDICAL RECORD, that the manufacture of the remedy is protected by international patents, but added that the profits of the sale would not go to Ehrlich, who is already immensely wealthy, but would go one-half to Speyer House, a research institution in Frankfort, and the other half probably to the manufacturers. At the conclusion of Dr. Mark's announcement the physicians present unanimously adopted a resolution recognizing the justice of Ehrlich's guaranteeing himself a legal control of his remedy by taking out international patents.

Protest Against the New Drug Law.—Representatives of many of the druggists' associations of New York met on September 6 at the College of Pharmacy and passed a protest against the recent ordinance of the Board of Health prohibiting the sale of medicines containing morphine or opium or their derivatives, except on a physician's prescription. A committee was appointed to consult with the Board of Health and attempt to effect a compromise. The druggists declare that the ordinance is too indefinite in not stating in exactly what quantities morphine can be sold, and that it restricts the sale of only some of the preparations containing morphine.

Gifts to Charities.—By the death of Mrs. Clara L. Dotger, a number of legacies provided for in the will of her husband, Andrew J. Dotger of South Orange, N. J., who died in 1905, are released. Among these are gifts of $10,000 each to the German Hospital of Philadelphia and the Orange Memorial Hospital.

Announcement has been made of the gift of $500,000 to the Evanston (Ill.) Hospital Association by Mr. George W. Patten. The money is to form an endowment fund for the Evanston Hospital to be known as the Agnes and Louise Patten Fund, in memory of the donor's mother and sister.

The First Trials of 606 in New York.—Dr. M. S. Kakels of this city has been using the Ehrlich-Hata remedy at the Lebanon Hospital in a few selected cases during the past two or three weeks. A preliminary note describing the remarkable results obtained by him will appear in the next issue of the MEDICAL RECORD.

Dr. George Francis Heath, who died in 1908, was remembered at the convention of the American Numismatic Society, of which he was the founder, on September 7, when the president of the Association made an address in appreciation of his life and work.

The Seventh International Tuberculosis Congress will be held in Rome September 24 to 30, 1911, under the patronage of the King and Queen of Italy. The Secretary-General is Professor Vittorio Ascoli, and the President Professor Guido Baccelli. The Congress will be in three sections, that on etiology and causes of tuberculosis; on pathology and therapeutics, both medical and surgical; and on the social defence against tuberculosis. The names of the presidents of these sections will be announced in the near future. The National Association for the Study and Prevention of Tuberculosis states that the American Committee will be able to announce that the number of tuberculosis agencies in this country has tripled in the three years since the last International Congress, and that more than twice as much money is being spent in the fight against consumption by private societies and institutions, and also that the appropriations for tuberculosis work by federal, state, municipal, and county authorities have quadrupled.

The Utah County (Utah) Medical Society at its regular meeting at Provo on August 29, elected Dr. H. G. Merrill to fill the office of secretary and treasurer made vacant by the resignation of Dr. Frederic Clift.

The Central Oklahoma Medical Association will hold its annual meeting at Chickasha on October 4. Dr. E. D. Ebright of Enid, Okla., is the secretary of the organization.

Obituary Notes.—Dr. ELY VANDEWARKER, a retired physician and former School Commissioner of Syracuse, N. Y., a graduate of the Albany Medical College in the class of 1863, a veteran of the Civil War, a member of the American Gynecological Society, and of the New York State and Onondaga County Medical Societies, and consulting surgeon to the Syracuse Hospital for Women and Children, and the Central Hospital of New York, died at his

home on September 6, after a long illness, aged 69 years.

Dr. Edward L. Pearce of Louisville, Ky., a graduate of the Medical Department of the University of Louisville in 1886, a member of the American Medical Association and the Kentucky State and Jefferson County Medical Societies, formerly surgeon for the Illinois Central and the Louisville Legion, died at his home on August 23.

Dr. James Meredith Matthews, a retired practitioner of Reading, Pa., a graduate of the Jefferson Medical College of Philadelphia in 1840, died at his home recently, aged 94 years.

Dr. James H. McInerny of New York, a graduate of the Yale Medical School in the class of 1891, a member of the New York State and County Medical Societies, and assistant surgeon to the General Memorial Hospital, died of heart disease at his summer home in Mount Vernon, N. Y., on September 5, aged 40 years.

Dr. James Nevins Hyde of Chicago, Ill., a graduate of the Department of Medicine of the University of Pennsylvania in the class of 1869; a member of the International Dermatological Congress, the American Dermatological Association, the British Medical Association, the American Medical Association, and the Congress of American Physicians and Surgeons, a corresponding member of the Berlin and Paris Dermatological Societies, and the Chicago Medical Society, dermatologist to the Michael Reese, Presbyterian, and Augustana Hospitals of Chicago, and Professor of Skin, Genito-Urinary and Venereal Diseases in the Rush Medical College, died suddenly on September 6 at his summer home at Trout's Neck, Me., aged 70 years.

Dr. Ferdinand A. Steffen of College Point, N. Y., a graduate of the University of Griefswald in 1882, died of apoplexy at his home on September 9, aged 53 years.

Dr. William E. Pole of Philadelphia, Pa., a graduate of the Jefferson Medical College in the class of 1890, died on August 29, aged 42 years.

Dr. James Cowan, a pioneer settler of Portage la Prairie, Manitoba, a graduate of the Medical Department of Victoria College in the class of 1862, died at his home on September 1, aged 70 years.

Dr. David W. Vander Burgh of Fall River, Mass., a graduate of the Department of Medicine and Surgery of the University of Michigan in the class of 1866, a veteran of the Civil War, and a member of the Massachusetts Homeopathic Medical Society and the American Institute of Homeopathy, died at his home on August 29, aged 68 years.

Dr. Harold L. Barnum of Sedalia, Mo., a graduate of the Hahnemann Medical College of Philadelphia in the class of 1902, died suddenly at his home on August 30, aged 36 years.

Dr. Timothy D. Sullivan of Calais, Me., a graduate of the Bellevue Hospital Medical College, New York, in the class of 1884, a United States Special Pension Examining Surgeon, and a member of the Maine Medical Association, and of the Portland Medical Club, died at his home suddenly on September 2.

Dr. Stuart A. Ashton of Ballston, Va., a graduate of the University College of Medicine of Richmond in the class of 1902, a member of the Virginia Board of Health, died of paralysis in Washington on September 9.

Dr. Simeon S. French of Battle Creek, Mich., a graduate of the Geneva (N. Y.) Medical College in 1842, died on September 10, aged 94 years.

Obituary.

EMILY BLACKWELL, M.D.

NEW YORK.

Dr. Emily Blackwell, a sister of the late Dr. Elizabeth Blackwell, in conjunction with whom she founded the New York Infirmary for Women and Children, died at her summer home, York Cliffs, Me., on September 8. Dr. Blackwell was born in Bristol, England, in 1826, but removed with her family to this country in 1832. Her struggles to obtain a medical education were indicative of the prejudices of the time. In 1851 she was refused admission to the Geneva Medical School, from which her sister had been graduated two years before, although the authorities were compelled to admit that the presence of Elizabeth Blackwell "had exercised a beneficial influence upon her fellow students in all respects." In succession ten medical colleges refused to enter her as a student, but finally she was permitted to pursue her studies at the Bellevue Medical College in New York, and a year later the Rush Medical College of Chicago consented to admit her to its classes. This permission was later withdrawn, however, because of the censure of the Illinois State Medical Association. At length the Cleveland Medical College, the Medical Department of Western Reserve College, admitted her, and in 1854 she received the degree of doctor of medicine from this institution. After further study abroad Dr. Blackwell returned to practise in New York, and together with her sister undertook to enable other women to enter their profession. It was decided that the greatest need was for a hospital in which women might obtain the experience not offered to them elsewhere, but the proposal to open such an institution, in which the attending physicians should be women, was met by a storm of disapproval. All difficulties were, however, overcome, and in 1865 the New York Legislature granted a charter to the New York Infirmary for Women and Children, a number of eminent men physicians acting as a consulting board. In 1868 the Woman's Medical College was opened in connection with the Infirmary, and the first class was graduated in 1870. In 1899 the college courses were discontinued. Dr. Blackwell remained on the consulting staff of the Infirmary until her death.

MEDICAL WORK IN WAR—KING EDWARD'S HOSPITAL FUND—CEREBROSPINAL MENINGITIS—ABDOMINAL OPERATIONS—PTOMAIN POISONING—GASTROENTERITIS—RESTRICTED DIET IN SKIN DISEASES—OBITUARY.

London, August 26, 1910.

Medical work in war has been illustrated this week by a series of tactical operations extending over three days and having as object the training of the R. A. M. C. units and hospital staffs after the manner of the military maneuvers. There was accordingly a sham battle and a realistic display as far as could be of the actual work of the army medical service in collecting the wounded on the field and transferring them to railhead. Here a new unit of the medical service, a clearing hospital, was established, as in the South African War. There was a congested condition of the field hospitals after a heavy engagement. So this clearing hospital plan was adopted and the maneuvers tested its efficiency. It seems to have given satisfaction to the military officers who commanded the troops engaged, who belonged to the regulars. Major-General

Sir H. Rawlinson, director of the operations, and Surgeon-General Balstie closely watched the proceedings. Perhaps the hardest day was Tuesday, when 1,345 were passed through the clearing hospital. The total for the three days was nearly 2,000. It is generally said that no department of the army has more studied and profited by the lessons of the last war than the R. A. M. C.

King Edward's Hospital Fund has issued the annual report concerning the accounts of 99 London hospitals. This gives an account of the expenditure and contributes to economy. The reduction of cost since the issue of these reports has been continuous and it may perhaps be that so much has been done that the same rate can hardly be expected. Taking everything into consideration it would appear that about £6,000 represents real progress in the direction of increased economy during the year 1909.

An outbreak of cerebrospinal meningitis in Leicestershire is creating anxiety. It began in one of the villages of the Vale of Belvoir but rapidly spread to others, ten being already infected. The first announcement was soon followed by the report of a death and four have been notified up to date. This morning it is stated that three cases have also occurred in Nottingham, one of which died last night. Three years ago there was a severe outbreak in this town. At both places the medical officers of health are exercising all their authority and are advising the inhabitants to take other precautions which they have not power to insist upon.

Considering the opinions expressed by some of our surgical authorities as recorded in your reports of the B. M. A. it may interest your readers to notice some outside views, such as those strongly emphasized by Professor Dieulafoy. Dr. Bradshaw of Liverpool doubts whether a differential diagnosis between gastric and duodenal ulcer is practicable unless exceptional conditions assist and when the so-called triad of symptoms (pain, vomiting, and hematemesis or melena) is present there is abundant room for doubt. Vomiting of blood and melena may be due to other causes. The relation of gastric ulcer to appendicitis seems more doubtful than does colitis, which has too often served as a cover for mistaken diagnosis and consequent unnecessary operation. When no ulcer has been found it is assumed that the appendix is the seat of the disease—just as when that part has been removed and found normal the error is attributed to muco-colitis. Very similar remarks may be made about cancer of the stomach, which causes some 5,000 deaths a year in this country. It was said that in the early stage the disease was only local and should be diagnosed before a tumor can be felt. But how? We might set up another triad (anorexia, anemia and debility), but who would recommend operation on these? They are common to so many lesions. In cases much more advanced mistakes have been many. The "leather bottle" stomach, long regarded as cancerous, is now held to be a fibromatosis. Microscopic examination has shown that in a considerable proportion of resections performed the disease was not cancerous.

Prof. Dieulafoy—I quote a Paris authority rather than any London neighbors—in a lecture at the Hotel Dieu which he has just published, reiterates with great force his opinion that many unnecessary operations have been performed for appendicitis—upon patients who were suffering for the most part from muco-membranous enterocolitis. When the exercised appendix was found normal an attempt to set up the defence of a microscopical inflammation is severely dealt with. He details no less than seventeen cases of useless appendicotomy, in all of which the patients continued to suffer just the same as before the operation. He adds that during the current year he has saved no fewer than fifteen persons from being operated on for appendicitis which had no existence.

Many cases of illness attributed to ptomain poisoning have been reported from Cheshire and Wales. Three deaths have taken place in about eighty cases. All the cases are said to have followed eating pork pies. In one inquest the jury gave a verdict of ptomain poisoning according to the doctor's evidence.

The patients seem to have suffered from acute gastro-enteric derangement and inflammation. I saw one lately in London which suggested serious illness and as a typhoid case had been visited by the patient's medical man feared that it might be contract disease. But it recovered in a few days and no bacterial examination had been made; or it would have been interesting to look for paratyphus and compare the case with those of Dr. Bainbridge, of the Lister Institute, who has related an outbreak of gastroenteritis due to *Bacillus paratyphosus B.* affecting fourteen persons. They were seized with vomiting, diarrhea and pyrexia (temperature 101 to 103 F.). No other symptoms suggestive of typhoid. Some of the patients made a very slow recovery; in fact, convalescence generally was delayed and the circulation in three so weak as to threaten failure. Three specimens of feces were examined. In two a bacillus was found practically identical with paratyphosus B. Blood from six patients agglutinated this as well as standard strains. No single article of food had been eaten by all the patients, the cases had not occurred in one household, and the dates of attack differed. So food seemed excluded. The possibility of a typhoid carrier was suggested and one person who was not attacked and whose blood agglutinated *B. paratyphosus,* was thought a possible carrier. But then attacks of gastroenteritis caused by this bacillus have not previously been recorded in this country.

I hear that the dermatologists are not particularly pleased with their section at the late meeting. Some appear to have been left out and think it was intentional. But I do not enter into the matter which would scarcely interest you. In this section the paper of Dr. Bulkley on a very restricted diet was welcome. You are, of course, familiar with his views, as some of them have been fully stated in your own columns. Here they are not quite so well known. He was able to assure us that his restricted diet, which he has been using for four years, has given striking results in lichen planus, dermatitis herpetiformis and urticaria. Acute eczema had rapidly yielded to the plan. A patient is confined to rice and white bread and butter for five days; milk, coffee, tea, cocoa all being excluded. Then a moderate mixed meal at midday permitted—the morning and evening meals being unchanged. A few days later some relaxation of the rule at breakfast is permitted, but the evening meal is to remain the same for a good while. He emphasized the importance of cooking the rice in water and never in milk. It should be cooked slowly and left uncovered over the fire until dry and flaky and should be eaten with butter and salt, masticating it well. Water would be taken as desired. Later milk might be permitted before the evening milk.

Dr. Unna commended Dr. Bulkley's plan as rational and far more practical than giving a patient a list of foods to be avoided.

Dr. Hartzell doubted the use of vegetarian diet in psoriasis and whether we could found a diet for eczema on scientific principles.

Dr. Eddowes found the new lactic acid treatment of use. Dr. Wild held that we have only opinions about diet in skin diseases—no rules really based on physiological knowledge. Dr. Bulkley's low diet would benefit patients who had been too well fed, but hospital cases were usually ill nourished and improved with better feeding. Dr. Walsh said alcohol, some drugs, as iodine and copaiba, and toxins, were excreted through the skin as well as other organs. Dr. Knowsley spoke of gout and the ill effects of alcohol on the skin. Dr. Bulkley in reply said his views were the result of experience in private practice. The uncertainty of hospital experience in skin cases was notorious.

The death of Dr. David Howard Reynolds, J. P., is reported at the age of 68. He was M. O. H. for Pembroke, Surgeon to the Infirmary, a magistrate for the Borough. He qualified in London 1865 and Edinburgh 1867.

Dr. Beresford N. Earle has died at 66. He was physician to the Royal Hants Hospital and M. O. H. or public analyst for Winchester.

Sir Constantine Holman died on the 18th inst., full of years and honor. He reached his 80th year through a strenuous life as a general practitioner and as one always before the professional public as promoting all its benevolent institutions. He was treasurer of the Epsom College Medical College, and for several years also of the British Medical Association. He took M.D., St. Andrews, in 1851. He was knighted in 1904.

A Diagnostic Sign of Whooping Cough.—Apest regards the superficial ulceration of the prenulum linguæ, sometimes seen in pertussis, as pathognomic of this disease. The ulceration is situated in the median line, on the free border of the prenulum, it is usually linear, and is sometimes covered with a false membrane. In 252 cases of pertussis the ulceration was present in 111.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

THE VIRCHOW MEMORIAL—A NEW KAISER WILHELM ACADEMY—RETIREMENT OF SENATOR AND OLSHAUSEN.

BERLIN, Aug. 25, 1910.

If I begin this letter with the recently unveiled memorial to Virchow, it is because I am certain as to its general interest, so many times has it been asked "why has it taken so long for Berlin to erect a worthy memorial to the greatest of its medical men?" Two tendencies in the Memorial Commission have pulled in different directions. One rejected entirely the design of the sculptor that the memorial should be conceived essentially as an allegorical glorification of his subject, while the other would depart directly from the eternal monotony of a sitting or standing figure. The two opposing forces compromised on a middle course; but before this compromise could be effected years elapsed. The site, as such, is well chosen. On the Karlsplatz, at the entrance, so to speak, of the Charité, where he spent the greater portion of his life and where he passed by innumerable times, Virchow's memorial is now erected. Perhaps a more restful spot would have seemed appropriate, so that to this great spirit some moments of meditation might have been consecrated by the public, undisturbed by the ever-passing street traffic. Yet it is exactly amid the rushing life of the hour that Virchow's memorial belongs, for his labors essentially concerned the public; here he sought his kind as selectman and as state and parliamentary representative.

Upon a firm pedestal a powerfully conceived male figure strives, with his entire musculature tense, against a monster. The latter raises its head with a menacing and baleful air, yet the man appears the stronger. The next moment would see the creature dead upon the ground. It would hardly be possible to imagine the multiform life of Virchow in a simpler or more beautiful manner. Whatever Virchow did represented a struggle against the powers that be. In order that the spectator may understand whom the design commemorates Virchow's image, in relief, is placed on the front face of the pedestal. The inspired features of the savant find here their lifelike counterpart. But in addition his actual professional activity finds its expression on the memorial. Upon the side facing the Charité Virchow is represented in the act of instructing a number of physicians at the autopsy table.

Pedestrians in the Friedrichstrasse—one of our great business and traffic thoroughfares—were quite recently astonished at a spectacle not common in this quarter. At almost any time of the day one might see at the Friedrichstrasse Bahnhof, at the intersection point of the most hurried thronging, young men leaning out from the windows of a large, plain building, and viewing with cheerful quietude the rushing traffic in the streets beneath. These were none other than the pupils of our military medical teaching institute, the Kaiser Wilhelm Academy. Recently the new structure, which is seated behind the Charité, has been occupied after a five-year building period, and now appears in brilliant attire. At the dedication exercises the Emperor and Empress took part along with the representatives of military and medical Berlin. The exercises which attended the laying of the keystone were very brilliant. The Emperor himself spoke with his three hammer strokes the words: "To ease the dying; to strengthen the healthy; to destroy pestilences." The words placed over the entrance of the building were also chosen by the Emperor: "Scientiæ, Humanitati, Patriæ." The entire buildings are arranged about a court bright with verdure, in which the memorial to the founder of the institution—Goerke—stands. A majestic gate with standing figures of Hygiea and Aesculapius on either side leads the visitor into the main building, which stands upon the street and contains an aula intended to accommodate 600 persons, museums, assembly rooms, and the far-famed library with its 67,000 volumes. The Casino lies adjoining the main building. Its ground floor is for the students, while two upper floors are intended for the sanitary officers. Dining, reading, and amusement rooms, with turning and fencing rooms, are located in the Casino. The dormitories are provided with accommodations for 300 students, two of whom usually share a living and sleeping room, although a single student may occupy one room if desired. Lecture rooms and laboratories occupy special buildings, and are unsurpassed models of their kind.

With the end of the semester just closed two Berlin physicians have left forever their teaching chairs—Hermann Senator and the gynecologist Robert Olshausen. In the great auditorium of the University Poliklinik the last lecture of Senator was heard on the occasion of the close of his forty-two years' activity as a teacher, this constituting an impressive ceremony.

After an address of parting delivered by Professor Richter, the oldest assistant, Professor Krause sketched the evolution of Senator's career, and emphasized the number of fields in which the latter had shown itself fruitful in works of fundamental importance. Senator had always been especially popular as a teacher. The number of his students had never been equaled by any Berlin professor. The speaker expected in the future that many more scientific achievements would follow the inexhaustible activity of Senator. With a voice tremulous with emotion Senator himself outlined a retrospect of the development of scientific medicine during the second half of the last century, in the course of which he emphasized especially the great deeds of other renowned physicians, as Garrod, Charcot, and Koch; so that the speaker in his modesty understood how to divert all progress to the credit of others.

Olshausen in his last address drew a comparison before a numerous audience between the present state of medicine and that of fifty-eight years before, when he began his studies. He sketched the early days of gynecology, especially at the time when the first laparotomy was performed. After addresses by his successor, Bumm, and an assistant, Olshausen thanked all in moving words.

NEURALGIA FOLLOWING THE USE OF SOLID CARBON DIOXIDE.

To the Editor of The Medical Record:

Sir:—Though much has been written about solid carbon dioxide, no reference has been made as to its action upon the nervous system. We find that its mode of preparation, its mode of application, and its uses have been described. At Lebanon Hospital (service of Dr. Gottheil) we have repeatedly used the CO_2 for lupus erythematosus, nævi, epitheliomata, etc., and mostly with excellent results; but in two cases treated there, and also in one treated in private, it was noticed that when the CO_2 was applied it caused a distinct neuralgia. In one case (Mr. M. B.) where the carbon dioxide was applied to a lupus of the cheek, a neuralgia lasting about 12 hours was produced. This gradually wore off, and reappeared, but less severe, after the second application. This later attack lasted about two hours; but it did not recur at the third and subsequent applications. In another case (Mrs. M. R.) the CO_2 being used on a lupus of the upper lip, there appeared a neuralgia affecting the whole upper jaw and extending into the ear; but this lasted only a few minutes. In this patient each and every application was followed by a similar attack of short duration (from 5-10 minutes). In a third (private) case, nævus of the lower lip, where the CO_2 was applied to the mucosa, a sharp neuralgia lasting about 10 minutes occurred. As no second application was necessary in this case, we do not know whether the phenomenon would have recurred. These cases are interesting as they are the only ones we have encountered in the many we have seen in which neuralgia followed the use of the solid carbon dioxide.

1980 Seventh Avenue, New York.

Progress of Medical Science.

New York Medical Journal, September 3, 1910.

The Treatment of Epilepsy with Hypodermic Injections of Rattlesnake Venom (Crotalin).—Ralph H. Spangler presents a preliminary report of 11 cases of epilepsy injected with this solution, made up of crotalus venom, ½ grain; glycerin, 50 minims; distilled water, 200 minims. Five minims of the solution contains 1/100 grain of the venom. He usually starts with 1/200 grain and gradually increases the dose, the largest dose being 1/12 grain. From his observations of these cases the following conclusions are drawn: (1) The number of cases have been too few, and the time they have been under treatment and observation too limited to arrive at positive conclusions. (2) In each case, however, the attacks have been modified as to severity and the intervals between the attacks lengthened. In one patient who had been subject to convulsions for six months there has been no recurrence since crotalin injections were begun. (3) The local reaction varies with individual susceptibility, and as a rule the oftener the injections are given the less marked

the local reaction. (4) There has been no depressing effect noticed on any of the vital functions of the system, but in all cases a feeling of well-being is described. (5) The physiological action of the venom on the nervous system needs further study and investigation.

Ichthyol.—Robert H. M. Dawbarn relates an instance in which mercurial ointment containing 25 per cent. ichthyol as a diluent was applied over an orchitis and acted as a violent irritant. After discussing the case with dermatologists and reading the literature on the subject it occurred to Dr. Dawbarn that ichthyol, being the fossilized remains of great masses of fish, it was quite possible that in prehistoric times, as well as at the present time, there would be among so many fish some of a poisonous nature. The writer could see no reason to assume that such animal poison necessarily would die out into innocence. Indeed, it might become even more virulent in time. Ptomains and toxins which are volative do not escape readily from within the earth and disappear as one might perhaps expect.

A Few Facts Concerning the Causes of Failures in Adenoidectomies.—J. Vernon White refers to the differences in construction of the nasopharynx in adults and in children; in children the measurements are all lessened and the vertical diameter is relatively shorter than in adults. He believes that a disregard of these differences of construction is a common cause of failure to relieve patients after adenoid operations. Peculiarities in the shape of the space on either side of the rostrum of the sphenoid bone and the location of the fossa of Rosenmuller and its relation to the Eustachian tube should be carefully noted and the operator should make sure that no vegetations are present in these localities, or if present, that they are thoroughly removed. This should be done by means of the finger, as there is danger of too much bruising or tearing of the tissues with the instruments ordinarily used. The condition known as Thornwald's disease should be looked for and treated if it is found to exist. With these precautions many of the failures hitherto so common will be a thing of the past.

Alcoholic Amnesia, with a Clinical Report of a Case.—N. S. Yawger says that among the various forms of mental disturbance is diminution or loss of memory. This may result from different causes, an important group being due to intoxications, and the particular intoxicant concerned in the case he reports is alcohol. This was a very grave case of complete alcoholic amnesia, and he feels reasonably sure that the psychic treatment which the man received almost daily for several weeks shortened very materially his illness, and perhaps saved him from permanent mental disability.

The Journal of the American Medical Association, September 3, 1910.

Blood-Pressure Apparatus.—C. F. Hoover criticises the dependence placed on blood-pressure determinations by laboratory apparatus in clinical work. Since the sphygmomanometer has been devised, there seems to be a general concession by clinicians that endovascular blood-pressure can only be measured by instrumental means and that finger palpation is misleading. He admits the difficulty of determining the pressure by the radial or brachial artery. The only artery which really serves for this purpose is the femoral, which gives practically the lateral pressure on the abdominal aorta and lies on the pubis under the mastery of the finger. It has lately, however, been apparent that either high endovascular pressure does not tax the heart so severely as we formerly believed, or that measurements have been misleading. He illustrates his view by reports of cases and experiments showing how fallacious or inefficient instrumental work in this line may possibly be. During the past four years it has been his practice to estimate the arterial pressure by palpating the femoral artery, and afterward to use the blood-pressure apparatus. A little practice will enable one to estimate the blood-pressure very accurately. In pressure between 150 mm. Hg. and 250 mm. Hg. he finds that there is rarely a disparity of more than 20 mm. between the digital and instrumental estimates, and as a rule the disparity is within 10 mm. He does not wish, he says, to discourage the use of a blood-pressure apparatus; it is a very valuable instrument, but its chief value consists in teaching us how to palpate the arterial pulse. No instrument can take the place of the finger, nor can any instrument teach as much about the pulse as can be learned by palpation.

Typhoid Fever Problems.—W. F. Dutton criticises the United States Government for its ineffective work in regard to the prevention of typhoid, as compared with that against some other diseases. It has been a comparatively recent thing for States and municipalities to take up this subject, and it has been especially neglected in the rural districts. In northern Canada, during 1909, typhoid appeared to be generally epidemic, especially in the mining regions. The only preventive measures used are the occasional disinfection of stools and urine with chloride of lime or bichloride of mercury, and the boiling of drinking water. Contaminated springs and wells are not condemned, but are cleaned out, sprinkled with lime or salt, and used again. Dutton has personal knowledge of wells that have been the source of typhoid for years, but any reference to them as a means of infection is received with apathy by the consumers of the water. Present day problems concern first the individual; second, the community, and third, the State. The individual in health may be the means of carrying and distributing typhoid germs, and Dutton believes that through errors of diet the colon, paratyphoid, or typhoid bacilli may generate typhoid. The individual must be educated to know the perils and avoid them. The problem of the community is a little more difficult. There may be many sources of infection and the situation may be complicated by restricted powers of control. A commendable procedure, however, is the isolation of bacillus carriers until microbes are no longer found in them, especially when they are persons employed as teachers, nurses, cooks, or employees in bakeries, dairies, restaurants, etc. Hospitals especially should regulate their subordinate staff and physicians should keep a record of all typhoid cases and systematize the record of carriers of the bacillus. The prevailing idea that healthy persons cannot be brought under control like other carriers needs serious consideration. The State is the great supervisor of medicine and public health, and Dutton mentions especially the work done in Pennsylvania in this regard. The water supply in small towns and rural districts presents a more difficult problem than that in larger cities, and he illustrates the sanitary methods that should be used in such communities. Municipal sanitation has taken a forward step in the disposal of garbage. The present method of constructing cesspools and vaults is faulty and needs strict regulation. The insect problem is also one to be considered. Vaccination against typhoid is in its infancy, but Dutton believes that it has a future and will become effective and valuable. He holds that the State should be the supervisor of all water supplies for cooking and drinking purposes. It should specify the sources and how they are to be protected and otherwise prevent all violations of hygienic or sanitary rules.

Subnormal Temperature in Infancy.—H. W. Cheney asks if we have not as physicians been too prone to disregard subnormal temperature and consider fever alone as of clinical importance. He points out that the condition of low temperature is usually a serious one, especially in infants and the specially recorded cases were generally fatal. The conditions of regulation of body temperature are far from perfect in infants, and slight causes produce greater disturbances than in adults. Insufficient heat production may be due in young children to starvation or stenosis, infantile atrophy or athrepsia, to prematurity and inanition, and these are far more likely to affect young infants than such other causes as diarrheas or disturbed central heat regulation or drugs, anemia, diabetes, etc., which affect adults. It is needless to emphasize the fact that great care must be used in taking and recording temperature in infants. The rectal temperature is undoubtedly the most reliable and this was used in the case reported. The child was a babe 3 months old when first observations were made. For nearly 3 months the temperature was more or less subnormal, one day going as low as 89° F. and frequently reaching 92° and 93°. It was the exception for it to go up to 98° F., and only once did it go above it. Small amounts of whiskey reduced the temperature; hot water bags and hot water baths did not elevate it. The child's father was an alcoholic. When it left the hospital it was slowly gaining in weight, but the temperature was still subnormal. The author thinks that this would fall under the head of subnormal temperature, due to insufficient heat production. The child was not active and resembled a premature infant. It lacked the life and vigor of a normal child. There is no doubt, he says, that the condition of inanition had much to do with the low temperature. Its weight varied from 4½ pounds on admission to 5½ on discharge, though the age at the latter was 7½ months. Cheney suggests the question whether there is anything in this condition analogous to the so-called hibernation of animals, but the subnormal temperature and inactivity are the only points of resemblance. There was no lowered respiration or heart beat in this case and food was taken regularly.

Vocal Cords in Goiter.—J. Matthews reports observations on the vocal cords in 1000 cases of goiter examined during the past 2 years. About 95 per cent. of the patients were operated on, and were examined before and reexamined after operation. After describing the motor nerve supply of the larynx and the liability to pressure from goiter, he summarizes his findings. There were 17 cases of paresis of both cords, 93 of the right cord and 162 of the left in the total of 289 partial or complete paralyses in 272 individuals of the 1000. Total paralysis of the right cord occurred 18 times; of the left, 30 times. Partial or complete abduction paralysis of the right occurred 50 times; of the left, 83 times. Partial loss of both motions of the right occurred 38 times; of the left 62 times. Bilateral tensor paralysis occurred in 4 cases. The paralyses were more frequent with enlargement of the right or left lobes. That of the median lobe alone was seldom accompanied by affection of the cords. The average frequency of symptoms of pressure on the nerves was directly proportional to the size of the lobes, but there were exceptions. Paralysis occurred sometimes when the lobe was not palpable, and in some cases with tremendous enlargement there was no affection of the cord. In 100 consecutive cases of nongoiterous patients there were 4 cases of paralysis. The position of the lobes was important. In goiters of the same size the cords were affected more frequently in cases with lobes located near the clavicle, especially if the goiter was wholly or in part intrathoracic. Firmness was likewise important, small, hard lobes being more likely to cause paralysis than large, soft ones. Long duration of goiter seems to increase the liability, both from its greater size and the long-continued pressure. Men are about three times as liable as women to paralysis from goiter of the same type. Exophthalmic goiter does not differ materially from other types in its effect on the cords except in extreme cases in which the general wasting of muscular tissues aggravates the condition. The age of the patient has no demonstrable relation to pressure on the recurrent laryngeal nerve except so far as goiters of large size and long duration occur in older individuals. No cases of recovery from total paralysis after operation are recorded, but in cases of short duration or when edema is a factor, there may be recovery. The importance of careful laryngoscopic examination is emphasized. It is essential to the prognosis of postoperative lesions, and might show the possibility of repairing damage by nerve suturing.

Stammering.—G. Hudson Makuen classifies stammerers as follows: First, those nervous children with any speech abnormalities; second, the beginning stammerers with hesitancy of speech; third, the complete stammerers, who know their defect. There are, therefore, three stages: the prodromal, the acute, and the chronic. For the first, the time to cure stammering is before it begins. Stammering is an acquired defect of an acquired faculty, and we should not let a stammerer hear others stammer when learning to talk. Ideation and oral expression are new to the child, and they do not acquire their normal automatic action, if ill guided. The treatment should begin at the kindergarten age, and the ideal place should be in a special hospital school away from relatives who, unfortunately, often lead the patient into the very fault they are trying to avoid. The treatment of the second stage, that of hesitation and frequent repetition of sound, is similar to that of the first with some additional measures. It is cruel to send such a child to school, and, as a rule, he should be kept in an atmosphere of good speech and drilled in all the elements of speech, together with respiratory, phonatory, and articulatory exercises. His defect should not be mentioned to him. In the fully developed defect the patient is apt to be discouraged as to his relief or to look to quacks. If he has weak will power he must be shown how to strengthen it. If he lacks attention and concentration or has grown morbidly introspective and self-conscious he must be shown how to get out of these conditions. He must learn self-control before he can control his speech. As regards specific methods, mental gymnastics, voice culture, and speech culture must form the basis of every rational treatment. The patient must learn the exact musculature of speech. One difficulty is that he tries to use the articulatory mechanism alone, apparently ignorant of the fact that the vocal mechanism should be used. In singing, he uses the latter, and therefore rarely stammers. It is a good practice, Makuen says, to drill in phonetic reading and what Dr. Bell calls syllabification. The individual must be taught to regard the organs of speech as an instrument on which he must play as he would play on a piano, and he must have the same facility that the pianist has with his fingers. Finally, as has been said, there are those who stammer and those who are stammerers, meaning, Makuen supposes, that we all stammer to some extent. But the stammerers are those who are conscious of their difficulties. A stammerer must learn that he can be cured. There is a field here for psychical treatment. Simple elocutionary measures may cure some, but there are some people so organized that it is very difficult for them to overcome the defect.

British Medical Journal, August 27, 1910.

Remarks on Some Points in the Treatment of Gastric Ulcer.—Charles Bolton points out that the series of cases of gastric ulcer treated by different methods that are constantly being published for the purpose of demonstrating that some particular method of treatment is the best are of little value because they fail to take into account the subsequent condition of the patient with regard to relapses of the symptoms. The diagnosis of gastric ulcer presents great difficulties and acute and chronic ulcer are usually not distinctly separated by the observer. Absolute freedom from symptoms during the intervals is in favor of acute ulcer, and the presence of some form of indigestion is in favor of chronic ulcer. Even though absolutely free intervals occur in chronic ulcer, it will be found that the patient is unable to eat a full diet. In regard to the treatment of acute ulcer, the writer agrees that perforating ulcer should be handed over to the surgeon at the very earliest possible moment. In case of hemorrhage the patient should be kept at absolute rest in bed, and morphine should be administered subcutaneously. After twelve hours has elapsed rectal feeding may be commenced, consisting of peptonized milk and glucose every six hours, the rectum being washed out each morning. When the bleeding has stopped for three days feeding by the mouth may be started and a simple enema given every other day. At the end of a week saline aperients are begun. The author does not employ rectal feeding in gastric ulcer under any other conditions. The patient is allowed to drink lime water frequently by teaspoonfuls. The really difficult point to settle is into what degree of danger should the patient be allowed to enter before the surgeon is called in. If a patient vomits two or three pints of blood and after an interval the clot breaks down and a similar amount is vomited, the case should be operated upon. In doubtful cases the most important point to take as a guide is the amount of the initial loss of blood. The most favorable diet is the milk and egg diet of Lenharz. The patient should be on a more or less full diet at the end of a month. The author has not found bismuth of any particular value, but sometimes uses dilute hydrocyanic acid, 5 minims in two teaspoonfuls of water for vomiting. The treatment of chronic gastric ulcer should be conducted on the same plan as that for acute ulcer, but should cover a much longer period of time. It is more necessary to give an alkaline fluid by the mouth in chronic ulcer as a large number of cases have hyperacidity. Iron should not be given until after the first six weeks. The icebag is used during hemorrhage, and hot poultices for the relief of pain at other times. Probably more than half the cases of true chronic ulcer should be treated surgically, but a three months' medical treatment should be tried first and prophylactic treatment should be adopted in all patients who have recovered from gastric ulcer.

Hepatic Abscess Following Acute Appendicitis.—Leonard A. Bidwell states that the occurrence of hepatic abscess after acute appendicitis is a very rare complication, and has usually been discovered at post mortem and that the abscesses were multiple, while in the two cases which he reports both were discovered during life and treated by operation. One of the cases was fatal, and he had the opportunity of examining the liver a week after opening the abscess and there was no evidence of another liver abscess. In these two cases the interval between the commencement of the disease and the detection of the abscess was eight weeks and four and one-half weeks, respectively. Both cases were apparently convalescent, with a normal temperature for the first fortnight after the operation on the appendix. In one case the abscess followed an operation for an appendix abscess, which was opened about three weeks after the initial attack and was thoroughly localized; in the second case the operation was performed for a perforated appendix with localized peritonitis within forty-eight hours of the onset of the disease. There is little doubt that the poison is carried to the liver by means of the portal vein, and that the abscess results from pylephlebitis. It is difficult during life to distinguish between hepatic and subphrenic abscess. The writer describes his method of opening and draining these abscesses and says that there is little

danger of trouble with the pleura, but there may be more danger of risk of infecting the subphrenic space; this occurred in the first case and was responsible for the fatal termination.

A Cause of Death After Operation for Appendicitis.—Herbert H. Brown calls attention to the frequent fatalities following operations for appendicitis, especially in children and in cases of localized abscess where the greatest care in operating has been exercised. He had lost four or five cases in this way in quick succession. In operating he had packed the inflammatory swelling around the appendix with gauze to shut off the peritoneal cavity. As pus escaped it was immediately mopped up with gauze. He continued this sponging until the abscess cavity was clean and dry. In studying these cases he had considered Nature's methods, and found that there are three lines of defense by which an organism defends itself against bacilli. The first line is the lymph agglutination of mesentery, intestines, etc., around the appendix, which prevents infection of the peritoneal cavity; the second line of defense is more important; it is the layer of lymph covering the surface of the intestine and omentum, and forming the wall of the abscess cavity; the third line is the blood itself, which protects by the formation of antibodies in the serum. In the cases to which the author refers the second line of defense was removed by too vigorous sponging and probably some infective material was rubbed into the surface of the unprotected abscess wall, causing an acute septicemia, and death resulted from invasion of the blood by the bacteria. According to this theory, the moral is obviously not to hurry to operate unless an operation can be performed within the first twenty-four hours. When a definite abscess has formed wait till after the first week, keeping the patient under close observation. Be contented to drain the cavity or use gentle flushing at the time of the operation. Above all things, if operating early, simply evacuate the pus without touching the abscess wall and leave the appendix to be dealt with later.

Berliner klinische Wochenschrift, August 15, 1910.

Alcohol in the Causation of Hepatic Cirrhosis.—Klopstock states that in alcoholics the general resistance to infectious diseases is lowered, as abundantly shown by the incidence of pneumonia, erysipelas and Asiatic cholera. Alcoholics are in the same manner exposed to infectious gastroenteritides of more or less doubtful nature, which cause a lowered resistance of the liver. The latter becomes unable to fulfil its disintoxicating function and becomes itself the seat of organic disease. Statistics show that in the great majority of alcoholics cirrhosis does not develop, and it is practically impossible to produce it experimentally. When cirrhosis does occur we find it often associated with enlarged spleen and a low degree of peritonitis. Such lesions cannot be set down as due to alcohol, although they may coexist with alcoholism. The association of hepatic cirrhosis, splenomegaly and chronic peritonitis argues a peculiar cause which is quite independent of alcohol. The abuse of the latter simply causes a sort of diathesis, through which patients are rendered less resistant to infection. The horse is subject to an endemic cirrhosis which may be hypertrophic or atrophic; this is ascribed to overfeeding with hay, which contains various toxic substances. Cattle in Nova Scotia have been attacked by an epidemic cirrhosis, associated with ascites and enlarged lymph nodes. Cirrhosis may be produced at will in certain animals by injection of any one of a great variety of microbes, some of which are naturally nonpathogenic. It would appear that any toxin, bacteriogenic or otherwise, may, when persistently exhibited, produce hepatic cirrhosis in animals.

Pulsus Paradoxus and Compression of the Subclavian.—Riebold states that pulsus paradoxus has been clinically important since Kussmaul pronounced it pathognomonic of chronic mediastinopericarditis. Since that period the phenomenon has been observed in connection with a great variety of different conditions. A physiological type is explained by negative pressure within the thorax, due to the act of inspiration, which gives rise to a slight fall of blood pressure. This type is demonstrable only by the sphygmograph. The phenomenon is regarded as practically the same for the two sides, although a difference appears in forced breathing. In pathological pulsus paradoxus the falling in blood pressure which constitutes the phenomenon becomes apparent to the finger. The author wishes merely to record that in his opinion certain cases (one of which he reports) have a purely mechanical cause, to wit: compression of the subclavian artery between the clavicle and first rib. It has long ago been shown that such compression may occur in deep breathing. A pulsus paradoxus due to such compression is revealed by elevating the shoulders of the patient, which separates the clavicle from the first rib. The author calls attention to the unwisdom of examining only the radial artery in pulsus paradoxus. The carotid should always be tested as well. When both vessels give an inspiratory intermittence, which disappears on raising the shoulders, the pulse is no longer paradoxal, but its cause is sufficiently explained. It then becomes a compression pulse.

The Fluoroscopic Screen as an Aid to the Removal of Foreign Bodies from the Bronchi and Esophagus.—Freudenthal evidently regards several cases of such removal as possessing world-wide interest, since he has recorded them in the *Wochenschrift*. The operators were F. Huber, R. T. Morris, and the author, respectively, all of New York. Two of the cases have been reported in medical journals of the United States. A third, undertaken by Freudenthal himself, consisted of removal of a nickel from the middle third of the esophagus (in the cases of Huber and Morris, a tack and pin, respectively, had been removed from a bronchus). Freudenthal's patient was but a year old. The screen, held by an assistant, showed the position of the coin, which was quickly extracted with forceps. It is conceded that the coin was removable by the old "blind" process, but the screen enabled the operator to save time and avoid bungling; and in the case of so young a patient he could hardly have availed himself of the esophagoscope.

Deutsche medizinische Wochenschrift, August 18, 1910.

Causes of Bromine Retention and Chlorine Displacement in the Blood Serum.—Frey, assistant to Prof. Kionka, of Jena, explains this phenomenon briefly by stating that these bodies—salts of chlorine and bromine—appear in the urine in the reciprocal relation in which they exist in the blood. The urine makes no distinction in their elimination. Hence, if there is poverty of chlorides, as in a salt free diet, flooding with bromides leads to a strong accumulation of the latter, which acts more rapidly than with a diet normal in salt. Conversely, when a patient has become bromized, and the remedy is stopped, the exhibition of chlorides hastens bromine elimination. Ten per cent. of the quantity of combined halogen injected is eliminated by the kidneys, so that if a single ordinary dose of sodium bromide is ingested much more chloride will be eliminated.

Syringomyelia in Mother and Daughter.—Goldbladt finds this coincidence of interest both as a contribution to recorded cases and as throwing some possible light on the disease. The cases themselves are interesting, because right-sided exophthalmus, a very rare symptom, was present in the daughter (but one prior observation is on record). Enophthalmus is fairly common. The exophthalmus was transitory, recurrent and doubtless connected with some fault of innervation in the sympathetic of reflex origin. About seven instances of familial syringomyelia were all that could be found in literature, the author's cases making eight. While the author believes that some necessary connection underlies the syringomyelia and exophthalmus, he goes no further than the intimation that the pathology of the sympathetic needs revision. Clinical and experimental findings do not agree. If we assume that the syringomyelia irritated the cord centers with which the sympathetic is connected, the symptoms should have been different. There should have been certain pupillary symptoms. On the other hand, atrophy of the facial muscles of the right side seemed to point to a paretic condition of the sympathetic.

Case of Purely Sensory Polyneuritis Alcoholica.—Pelz describes the case at length and sums it up as follows: A man who had been a heavy drinker for several years, and who before this history had suffered from arsenical polyneuritis, began to complain of severe pains in the hands and feet, with paresthesia and anesthesia. Occasionally he complained of the girdle feeling. There were no paralytic phenomena. He had the general symptoms of chronic alcoholism. There was loss of electric excitability and of the patellar and Achilles reflexes. The symptoms pointed to alcoholic polyneuritis or tabes dorsalis. The latter was gradually eliminated, chiefly because of the intact sphincters, but also by reason of other differences. Lumbar puncture gave a negative result. Ataxia was wholly absent, but its appearance might have been delayed. The case certainly could not be reckoned as one of so-called "false tabes," sometimes seen with toxic polyneuritis of any sort. This clinical type exhibits both ataxia and paralyses. The author is forced to regard his case as one of purely sensory alcoholic polyneuritis, one of the rarest of affections.

Book Reviews.

A Manual of Midwifery: for Students and Practitioners. By Henry Jellett, B.A., M.D. (Dub. Univ.), F.R.C.P.I., L.M.; King's Professor of Midwifery in the School of Physic, Trinity College, Dublin; Gynecologist to Sir Patrick Dun's Hospital; President of Obstetrical Section of the Royal Academy of Medicine in Ireland; late Gynecologist and Obstetric Physician to Dr. Stevens' Hospital, Dublin; ex-Assistant Master, Rotunda Hospital; late Extern. Examiner in Midwifery, Royal University of Ireland; late Censor and Examiner in Midwifery, Royal College of Physicians, Ireland; late University Examiner in Midwifery and Gynecology, Dublin University; late Vice-President of the British Gynecological Society. With the assistance in special subjects of: W. R. Dawson, M.D., F.R.C.P.I., Medical Superintendent Farnham House, Dublin; University Examiner in Forensic Medicine, Dublin University. H. C. Drury, M.D., F.R.C.P.I., Physician to Sir Patrick Dun's Hospital, and formerly Physician to Cork Street Fever Hospital, Dublin. T. G. Moorhead, M.D., F.R.C.P.I., Physician to the Royal City of Duhlin Hospital; late Chief Demonstrator in Anatomy, School of Physic, Trinity College, Dublin. R. J. Rowlette, M.D., Pathologist to the Rotunda Hospital and to Dr. Stevens' Hospital, Dublin; Lecturer on Pathology, Queen's College, Galway. Second Edition. With 17 plates and 557 illustrations in the text. New York: William Wood & Co., 1910.

In the second edition of this book the original text has been revised and brought in line with the recent advances in obstetrics. A number of new drawings have been introduced, and additional chapters added dealing with "Scopolamine-Morphine Anesthesia During Labor," "Pubiotomy," and "Vaginal Cesarean Section." In a chapter entitled "The Autointoxications of Pregnancy" are grouped acute yellow atrophy, hyperemesis gravidarum, and eclampsia. The book has been divided into ten parts, each section containing anywhere from two to ten chapters. In the first two parts are found chapters dealing with obstetrical anatomy, asepsis, antisepsis, diagnosis, and the obstetrical armamentarium. The remaining sections consider the physiology of pregnancy, of labor, and of the puerperium, the pathology of pregnancy, labor, and of the puerperium; obstetrical operations and the infant. In dealing with the pathological conditions incident to pregnancy the author gives in full various methods of treatment and states his preference.

The book is lucid in its description and concise and definite in its statements, making it extremely valuable for ready reference.

The Practical Medicine Series. Under the General Editorial Charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School, and Charles L. Mix, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School. Vol. I, General Medicine. Edited by Frank Billings, M.S., M.D., Head of the Medical Department and Dean of the Faculty of Rush Medical College, Chicago, and J. H. Salisbury, A.M., M.D., Professor of Medicine, Chicago Clinical School. Vol. II. General Surgery, Edited by John B. Murphy, A.M., M.D., LL.D., Professor of Surgery in the Northwestern University, Attending Surgeon and Chief of Staff of Mercy Hospital, Wesley Hospital, St. Joseph's Hospital, and Columbus Hospital; Consulting Surgeon to Cook County Hospital and Alexian Brothers' Hospital, Chicago, Ill. Vol. III. The Eye, Ear, Nose, and Throat, Edited by Casey A. Wood, C.M., M.D., D.C.L.; Albert H. Andrews, M.D., and Gustavus P. Head, M.D. Chicago: The Year Book Publishers, 1910.

We welcome the first three volumes of the 1910 edition of the "Practical Medicine Series." The series is an abstract of the literature of the past year, and through its use one may be able to keep up with the advances in the various fields of medical activity.

Volume I deals with the progress in general medicine. It covers diseases of the respiratory organs, of the circulatory and blood-making organs, of the blood and blood vessels, infectious diseases, diseases of the ductless glands, metabolic diseases, and diseases of the kidneys.

Volume II treats of the advances in general surgery. In the part devoted to anesthesia and analgesia the advantages and disadvantages of scopolamine and morphine have been discussed at some length. There are also articles on venous, arterial and spinal anesthesia, including Jonnesco's method. Under "Operative Technic" are two very interesting articles: One by Roswell Park, entitled "The Next Twenty-five Years in Surgery," and "Some Foreign Notes," by R. L. Dickinson.

Volume III is devoted to the diseases of the eye, the ear, and the nose and throat. The contents of the book are about equally divided among the three specialties. Treatment, improved methods of diagnosis, and the advances in operative technique are discussed, and new instruments are described.

The Metaphysics of the Nature and in the Conception of the Soul: Its Habitat? By Joseph Clements, M.D., Member of the American Association for the Advancement of Science. Boston: The Roxburgh Publishing Co. (Inc.).

In this little book the author gives his ideas of the origin, nature, and the location of the soul. He argues that the soul is independent of the physical, except in so far as the physical is used to express the characteristics of the soul. The author claims that the origin of the soul is in the human infant, and that heredity and environment play the most important part in the soul's development. To quote from the book: "The dawning soul is a plastic thing, and the mother-rôle and power in the immediately after-birth time is of marvelous effectiveness in psychic manipulation."

The Religio-Medical Masquerade. A Complete Exposure of Christian Science. By Frederick W. Peabody, LL.B., of the Boston Bar. The Hancock Press, Boston.

During the past ten years the author of this little book has devoted a large portion of his time to an investigation of the subject of Christian Science, and especially of the life history of its founder, Mrs. Eddy. As the attorney in nearly every lawsuit which has been brought against the sect or its leaders during the past decade it has been his duty to attempt to learn the truth as to the new religion, and as a result of careful reading of every word of Mrs. Eddy's writings, and of large numbers of personal letters, as well as of many hours spent in detective work as to her past life, Mr. Peabody may well be considered to know more about the inner workings of Christian Science than any other living person, except the founder of the religion and the small coterie by whom she is now surrounded in her prison house in Boston. In the present book Mr. Peabody has published the results of his years of investigation. He has not minced words. He has shown up the inconsistencies between Mrs. Eddy's own disreputable past and her comparing herself to the Christ. He has shown how her inspiration from God was a plagiarism from Quimby, and he has shown the purpose of it all—the collection of the shekels of the faithful. He furthermore dwells upon the modern version of the Salem witchcraft—malicious animal magnetism. Mr. Peabody is not afraid to say what he thinks. He courts libel suits. In his first expose, written nearly ten years ago, he asked that he be sued, and the request is repeated in the present book. The book is vituperative in character; immeasurable greed, sham religion, and foulest fraud are terms in frequent use. The purpose of the book is to show how thousands have been duped by "the greatest get-rich-quick concern ever conceived." The book makes decidedly interesting reading. It is to be hoped that some follower of Mrs. Eddy will take up the gauntlet and sue the author for libel. It would be interesting to see him present his proofs.

Spa Treatment. Selection of Patients and the Choice of A Suitable Spa. By Neville Wood, M.D., M.R.C.P. *"Ille terrarum mihi præter omnes angulus ridet."* London: Adlard and Son, 1910.

In this small book the author discusses the class of patients suitable for spa treatment, and the choice and climatic value of the different spas. He also considers the air, exercise and diet, the thermal influences, the value of mineral waters, and the aims and limitation of spa treatment.

Grundriss und Atlas der speziellen Chirurgie; von Prof. Dr. Georg Sultan. ii Teil mit 40 farbigen Tafeln und 261 zum Teil zwei—bis dreifarbigen Abbildungen nach Originalen von Maler Schmitson, Berlin. München: J. H. Lehmann's Verlag. 1910.

This book, like others of its class, depends for its value almost entirely upon the number and quality of its illustrations. Outside of these it contains little new or original, but it may be said of many of them that they contain more information than could possibly be put into text. The colored plates are very beautiful and are wonderfully well done. The others also are praiseworthy. The work forms the 37th volume of Lehmann's so-called hand-atlases.

Society Reports.

AMERICAN ORTHOPEDIC ASSOCIATION.

Annual Meeting Held in Washington, May 3-5, 1910.

Our Relations with the Cummunity, Especially with Medical Men.—Dr. Augustus Thorndike of Boston in his presidential address made a plea for orthopedic surgeons to take greater interest in the work of other members of the medical profession, and to try by every means in their power to interest other physicians in the work of the orthopedic surgeon.

Pott's Disease; Causes of Paraplegia and Their Bearing Upon Treatment.—Drs. Charles F. Painter and George C. Moore presented this paper, which began with a discussion of the various causes for the paralysis occurring in the course of Pott's disease, both in theory and as the result of actual observation. A study was made of the clinical phenomena, and of the behavior of the cases with and without treatment; also of museum specimens and of pathological material. A consideration of the rationale of the treatment, conservative and operation, was then taken up, and the following conclusions reached: Scoliosis occurring in Pott's disease should be regarded not as a regrettable incident in the course of the disease, but as an evidence of the activity of a tuberculous process. This fact should cause redoubled efforts on the part of the physician to control the underlying disease. So long as this exists, one should be cautious in giving a prognosis as to the cure of the condition. In seeking to relieve this condition, one should be guided by the character of the symptoms, and be loath to permit operative interference until further and more convincing evidence has been obtained that surgery can play any part in the cure of these conditions.

The Advantages of Braces Over Plaster Jackets in Pott's Disease.—Dr. Henry O. Feiss reviewed the evidence for and against plaster jackets, and found that they had many disadvantages. As regards fixation, he thought that a brace would do everything that a jacket could do. A brace can be readjusted to suit changes in size, and they are lighter than the plaster jackets. The parts are accessible, when braces are worn, so that the patient may be bathed. The jacket can be removed by the mother almost as easily as a brace, and the temptation to remove it is greater. The mother should be thoroughly instructed how to adjust the brace, which meets all the mechanical requirements, and is lighter, cleaner, cooler, and more scientific than the plaster jacket.

Support for the Spondylolytic Spine Obtained by Healing in Steel Bars Attached to the Vertebræ.—Prof. Fritz Lange, M. D., of Munich, said that the kind of metal used was of much importance. In this minor operation, designed to immobilize four or more of the vertebræ, he used steel wires, 5 mm. thick and 10 mm. long, which had been carefully plated with tin. The operation is applicable only in the early stages of the disease, before the appearance of deformity or when the deformity is slight. The wires employed have tin knobs at their upper and lower ends, and a thread is tied under the knobs, to prevent sinking. Provision is also made to fasten the apparatus to the spine. He believed that his new operation would give the best chance for spondylitis to be healed quickly and without great pain.

Dr. Newton M. Shaffer said that if in Pott's disease the trauma of respiration could be eliminated in the dorsal region, a long step in the right direction would have been taken; but that Pott's disease below the respiratory region required very little support. If the patient were studied before the support was applied it would be found that he made an effort to limit respiration in the affected area.

Dr. S. J. Hunkin agreed with Dr. Feiss that in a great majority of cases the steel braces could be applied with more efficiency than could the plaster jackets, but he did not think that a plaster jacket was heavier than a steel brace, if properly made.

Dr. Charlton Wallace said that all orthopedic surgeons should aim to give the patient the benefit of whatever treatment was the best, no matter whose it was. The treatment for Pott's disease should be selected according to the stage of the disease. He thought that the main object of the treatment, relief from the superincumbent weight, could best be accomplished by putting the patient to bed on a frame or some other reclining apparatus; but, as those who loved children hated to see them put to bed for several years, it was important to secure some proper method of ambulatory treatment. He thought it was foolish to claim that the spine could be absolutely immobilized, and considered the plaster jacket advantageous in controlling spinal movement in the early stages of the disease, after the patient had been taken from bed. He said that these jackets can be made to weigh as little as a pound to a pound and three-quarters. When the patient had become convalescent, he thought that the brace could be advantageously employed, but he did not believe that anyone could instill into the mothers a knowledge of the principles of orthopedic surgery within the few minutes allowed for consultation. He considered Prof. Lange's method of treatment hazardous, although admirable in the hands of an expert. He himself would be afraid to try it.

Dr. David Silver thought that the choice between jackets and braces depended upon which the particular orthopedist could handle best. He believed that the correction of the deformity should be accomplished during the period of recumbency, and not by means of the jackets or braces. The orthopedist should attend to changing the braces himself, and not allow the parents to touch them.

Dr. Ansel G. Cook said that the orthopedist should remember that he has a human being to treat, who sometimes needs the bed and sometimes fresh air. There were times when the jacket was better than the brace, and other times when the brace was very much better than the jacket.

Dr. H. Augustus Wilson said that the removal of the superincumbent weight was merely one of many means to the end. If this weight interfered with the circulatory activity it should be removed; and if recumbency in bed did not interfere with circulatory activity it was essential for a certain period of time. He had seen many cases cured without resort to apparatus, and considered the form of apparatus of minor importance, the constitutional treatment being of great importance. He believed it questionable whether Prof. Lange's method of treatment would be of much use to the ordinary orthopedic surgeon.

Dr. Robert S. Lovett thought that one should recognize the fact that neither the jacket nor the brace is thoroughly efficient mechanically for the removal of the superincumbent weight. Great as were the objections to the treatment of Pott's disease by means of recumbency, he considered it the only efficient surgical treatment for tuberculosis of the spine. Comparing treatment by means of braces and treatment by means of jackets was, in his opinion, comparing two relatively inefficient methods.

Dr. Reginald H. Sayre thought that in a rather larger number of instances than Dr. Painter had appeared to believe the superincumbent weight and a bending forward of the spine constituted large factors in the production of hemiplegia. He did not think that the use of the recumbent position, unless supplemented with longitudinal traction or hyperextension, would give adequate support. He considered a plaster jacket without a jury mast as often a very inefficient support. The mast should have a chin support and exert pressure against the anterior part

of the neck, to keep the upper part of the body well bent backward. He considered the difficulty in keeping the bones at rest insuperable. Dr. Lange's method, he said, should not be undertaken by anyone who had not very skilful technique. While he thought that it might be useful in suitable cases, he did not believe that in badly kyphosed cases the requisite amount of support could be obtained in this way.

Dr. B. K. McKenzie said that if treatment by means of recumbency must be given in a house, he was not sure whether he would choose it in preference to efficient mechanical support with a brace or jacket. The patient should live out of doors, day and night, and when the sun shone he should be directly exposed to its rays.

Dr. G. G. Davis said that for a number of years he had felt that the main drawback of orthopedic surgery was that the cases were too long under treatment. Inasmuch as Dr. Lange had carefully tried this operative method, Dr. Davis was of the opinion that a fair trial should be given it. It should receive consideration as being one of the measures in the direction of shortening the period of treatment.

Dr. James K. Young considered that a field for the operation of laminectomy existed in those cases in which the paralysis had lasted for a year or eighteen months, there being no improvement in the symptoms, or symptoms of abscesses having been verified by means of the *x*-ray.

Dr. Albert H. Freiberg said that treatment by means of recumbency was one of the very oldest methods used in cases of Pott's disease. It had gone out of use for a while, but was returning to favor. When patients with tubercular joint disease were put to bed they at first made a great improvement, but if the treatment by means of recumbency were continued longer than three months the patients began to retrograde. To prevent this retrogression the open-air treatment and the care of the patient's regenerative processes must be added to the recumbent treatment. Regarding Professor Lange's ingenious method Dr. Freiberg said that if the application of the splints were delayed too long they would be applied when the spine was no longer able to respond by the production of new bone tissue in the place of that destroyed by the disease.

Dr. Emil S. Geist said that it had struck him that as these incipient cases of Pott's disease are usually in children, the future growth of the spine should be considered, if Dr. Lange's steel bars were to remain attached to the vertebræ.

Dr. Painter, closing the discussion, said that he considered sclerosis the keynote to the treatment of Pott's disease by laminectomy. When the proliferation of connective tissue took place within the pia, laminectomy would do no good, although it would relieve a considerable part of the pressure. When the granulating process had produced changes outside the dura only, the paralysis could be relieved when the scar tissue had sufficiently shrunk. The paraplegic conditions that should not be touched under two years could not, he said, be relieved at the end of that time. The patients that got well did so because the process was outside the dura.

Dr. Fiss, closing, said that he believed recumbency to be the best treatment for Pott's disease, when it could be carried out. He had not said that the principles of plaster jackets were wrong, but that they could be carried out more accurately and scientifically by means of braces. He thought that it would be as difficult to teach the mother to put on the braces in the later stages of the disease as in the earlier.

Dr. Lange, closing, said that the operation recommended by him should be carried out as early as possible, the object being to secure the healing of the process before much destruction of tissue had occurred. He would not, however, hesitate to employ his method in cases in which the disease had progressed farther. In the case in which the longest time had elapsed since the operation, two years, he had not been able to observe by means of the *x*-ray that the vertebræ in the part of the spine spanned by the wires were smaller than those immediately above and below the point operated upon. Should he observe any interference with the growth of the spine, he would remove the steel wires after the disease had healed.

Treatment of Structural Scoliosis.—Dr. Walter Truslow stated that in his opinion the greatly embarrassing and often health depleting conditions of the severely scoliotic patient should be vigorously attacked. He did not consider either prolonged rest or vigorous gymnastic treatment adequate to overcome structural changes. He thought that there was considerable room for improvement in methods of treating these cases, and that an analysis of the deformity into its component elements, with regard to the degree of each, would lead to a better understanding of the cases in hand, and would point out the method of correction to be used. Frequently changed plaster-of-paris jackets with large windows were employed because of their cheapness and the adaptability of the material. He presented some advances in the technique, and reported distinct improvement in some patients with severe deformity.

Apparatus for the Treatment of Scoliosis During Sleep.—Dr. Fritz Lange exhibited a brace that he had devised for this purpose, thus preventing patients from losing at night all the good that they had acquired in the daytime.

Dr. Sayre said that patients that are badly deformed could not be cured, but that a good deal could be done for them. He considered that in a good many instances the orthopedist did not apply the force in the right way. He should exert a rotating force upon the vertebræ, in order to turn them; but he usually applied the force laterally. He considered Dr. Lange right in saying that to apply correction to the spine during the day and leave it to get crooked during the night was a very useless procedure. Regarding the length of the apparatus, Dr. Sayre said that if it stoped at the axilla it would leave the upper part of the body very much unprotected. He thought that enough stress had not been laid upon the necessity for preventing patients from becoming scoliotic by the use of traction to the head for a long time.

Dr. Freiberg exhibited an instrument for measuring the degree of scoliosis. It combined in one instrument measurements that had formerly required two, and was cheaper for Americans to obtain than the imported instruments.

Dr. Truslow, closing the discussion, said that he was glad that Professor Lange had felt the necessity for the fixation treatment. It seemed to him that the tendency of the times was certainly toward fixation in the treatment of this condition.

The Relation of Poliomyelitis to the Community with Reference to Etiology and Prevention.—Dr. Robert W. Lovett read an exhaustive paper on this subject, illustrated with charts containing statistics gathered from the Massachusetts epidemic that occurred last year. The following facts were mentioned: Outbreaks of infantile paralysis have greatly increased in various parts of the world within the last five years, in a measure not to be explained in any way by the increased interest in the disease. It is apparently more prevalent in warm than in cold countries. From the northern part of the United States more cases have been reported than from other parts of the world. We do not know by what channel the disease enters the body, nor how to prevent its spread. Careful investigations have been made, including a house-to-house canvass in infected districts, made by competent

medical men, giving their whole time to the investigation. The data given in the charts were merely submitted as part of an unfinished investigation, and no conclusions were drawn from them.

The Clinical Aspects of Poliomyelitis: Types; Communicability; Mortality.—Dr. L. Emmet Holt said that the disease varied greatly in its communicability at different times, and that these differences could not yet be reconciled. It often demands strict quarantine. Healthy persons may be carriers of infection, which may occur at a considerable time after contact with active cases. There is no evidence of the existence of any other medium of contagion than contact with persons suffering with the disease or those exposed to it. The author thought that a new name for the disease should be sought, and suggested the term epidemic myelitis or epidemic myeloencephalitis.

Experimental Epidemic Poliomyelitis and Its Relation to Human Beings.—Dr. Simon Flexner presented a report on the experimental study of poliomyelitis in monkeys, giving facts relating to the spontaneous disease in man. Dr. Flexner considered the active agent to belong to the class of filterable viruses; that is, viruses of ultramicroscopic size. There is no evidence of its being possible to cultivate it outside the body. The experimental disease is not only identical with the spontaneous in respect to its clinical appearances, but also in respect to its pathological lesions. The animal inoculated with the virus may remain in good health for sixty days afterward, when unmistakable symptoms of the disease appear. The chief seat of the disease is in the nervous system, and the membranes of the nose and throat become infected from proximity to the membranes of the brain and cord. Dr. Flexner thought it probable that the virus left the body through the nasal excretions, and entered the bodies of other persons through the same route. One attack confers immunity in the monkey and the blood of immunized animals will neutralize the virus. The blood of children recovering from poliomyelitis also possesses this power. The disease may be diagnosticated in the monkey by means of the cerebrospinal fluid, some time before the appearance of symptoms. It is a much more fatal disease in monkeys than in human beings, but these animals are not naturally subject to it, a certain amount of traumatism being required in order to allow the virus to gain entrance.

Paralysis of the Neck and Diaphragm in Poliomyelitis.—Dr. Irving M. Snow said that neck paralysis in combination with loss of power in the extremities was not unusual in poliomyelitis, but that isolated neck paralysis was extremely rare. Paralysis of the diaphragm was scarcely mentioned in treatises upon poliomyelitis, except in connection with the fatal type of Landry's paralysis. The author, from his study of the literature existing upon the subject, drew the following conclusions: (1) Cervical poliomyelitis affecting the origins of the phrenic and spinal accessory nerves is rare, but in the two reported cases recovery occurred. (2) Paralysis of the neck muscles occurs occasionally in epidemic poliomyelitis and severe Landry's paralysis. The prognosis is favorable as to restoration of function: some improvement always takes place. (3) a paralysis of the diaphragm is exceptionally seen in poliomyelitis; and although this is dangerous, recovery is possible.

Pathology of Poliomyelitis.—Dr. Israel Strauss said that the rapid disappearance of the extensive paralysis often present, even in sporadic cases of poliomyelitis, was probably due to a subsidence of the inflammatory edema that had interfered with the conductivity of the nerve fibers, a similar condition being found in the collateral edema causing paraplegia in Pott's disease. Many of the cells at any particular level of the cord would be either not at all or very slightly affected, and would probably undergo a rapid restoration of function. Sporadic cases rarely have symptoms referable to the meninges, probably because the virus is not virulent enough to cause the final infiltration of the fatal cases. The extent of the paralysis gives no idea of the extent of the lesion. The bulbar cases may have cord involvement, and yet no symptoms of it. In every case in which the cord is affected there are some inflammatory changes in the bulb, even though no symptoms are present. Dr. Strauss based this conclusion upon the fact that even in those cases in which death is due to respiratory failure an examination of the bulb shows an increasingly intense inflammation extending up into the basal ganglia, and yet causing no other symptoms than paralysis of the motor nucleus of the nasal and glossopharyngeal nerves. In the vast majority of cases the physician is handicapped by his inability to recognize the disease.

The Treatment of Poliomyelitis.—Dr. Fritz Lange said that in the early stage of the disease one should try to prevent the extension of the seat of the infection into the spinal column, and that holding the affected organ still was a most important requirement for speedy recovery. After the acute stage had passed, a second task devolved upon the orthopedist, to assist the restoration of the paralyzed muscles and prevent the occurrence of contractions. The nourishment of the affected muscles by the blood could be favored by the application of stimulation; but Dr. Lange warned physicians against the use of rough, hard massage, or of hard apparatus. He said that most patients were content with the relief afforded by the use of apparatus, and would not submit to operation, but that he had not seen undoubted success obtained by operative treatment. Patients are often troubled by stiffness of the foot in walking over irregular ground, and he had therefore sought an operation that would retain the movements of the foot to 90 degrees, and only restrain the dangerous sinking of the foot beyond this point. In performing this operation he had used artificial ligaments of silk; and he thought that the results would be good. Transplantation of the tendons takes the place of arthrodesis. He said that the chief advantages of his operation, which he described in detail, were perfect asepsis and the fact that, with careful after treatment, the patients were able to walk without apparatus or danger of relapse, and with normal function of the transplanted muscle. He thought that the profession would soon learn to distinguish better between the indications for arthrodesis and those for transplantation of tendons. The latter operation, having already brought benefit to countless patients, might be considered among the greatest advances in orthopedic surgery.

Dr. Bernard Sachs said that although much more than anterior poliomyelitis was present in this disease, as shown by pathological conditions, he thought that it would be well to retain this designation because it was so well known, and because the lesion was so largely in the cord. He considered the time given to massage and electricity in the treatment of this disease to be practically wasted. He could not say that this method of treatment did harm, but he had never seen any definite good done by it, and he believed that more good would be done by the early institution of orthopedic measures. He also trusted that both the bloodless and the bloody surgery would be applied, and thought that the sooner this was done the better would be the result. The so-called atypical forms of this disease being so rare as compared with the typical, he did not believe that one should allow one's conception of the disease to be disturbed by the occasional occurrence of atypical cases.

Dr. H. Winnett Orr said that he had been endeavoring to collect as much information as possible regarding the epidemic of poliomyelitis that had recently occurred in

Nebraska. He had reports of over six hundred cases, concerning two-thirds of which he had been able to obtain definite information. He had summarized this information in a little chart, which had been included in a pamphlet giving a statistical table of cases treated in the Nebraska State Orthopedic Hospital. He distributed copies of this pamphlet among the members, without further comment.

Muscle-Group Isolation and Nerve-Anastomosis in the Treatment of Paralyses of the Extremities.—Dr. Nathaniel Allison and Dr. Sidney L. Schwab considered briefly the position now occupied in the treatment of the paralysis of the extremities by peripheral nerve surgery as compared with that of muscle and tendon transference, and laid stress upon the importance of tabulating cases of paralysis of the extremities in terms of nerves, rather than in terms of muscles or deformities. They then gave a list of the types of paralysis that offered a suitable field in which to employ nerve anastomosis and muscle group isolation, and dwelt upon the value of a combination of these two procedures. Cases of athetosis and spasticity were treated by muscle group isolation only; flaccid paralyses, by muscle group isolation and nerve anastomosis, and cases with complicated tic movements, by induced paralysis. Illustrative cases of each of these groups were cited.

Dr. Schwab said that alcohol injections in spastic cases are not curative. All that the authors had attempted to do by means of them was temporarily to throw out of action the antagonistic muscles. Meanwhile, the opposing group of muscles was exercised, so that by the time the original nerve had regenerated the muscular force had been somewhat transferred to the opponent group. He also stated that under this mode of treatment the patient could be gotten out of bed within a few daysy, and there was no necessity for the use of a plaster cast. In the cases of flaccid paralysis the condition was more hopeful of future cure than by any other method. While cases of tic might not have the same amount of orthopedic interest, these cases could be attended to better than ever before by surgical treatment. While the nerves were alcoholized and there was complete anesthesia to touch and pain, no trophic disturbances appeared.

Dr. McKenzie asked for some particulars regarding the technique of the operation and the strength of the alcohol.

Dr. Davis said that alcohol injection of nerves was similar in its effects to division of nerves, the nerves resuming their functions in each case. If the nerves did not resume their functions absolutely after the alcohol injections this method of treatment was an advance; but Dr. Davis did not think that a sufficient number of good results had yet been shown to demonstrate that regeneration of the alcoholized nerves did not take place entirely, or to what extent it failed to return. Regarding treatment by nerve anastomosis, he said that a longer time must elapse before its value could be determined.

Dr. Virgil P. Gibney said that if the authors could destroy the action of these muscles for even a few months the opposing muscles could be developed in the interval, which could not be done when a plaster cast was worn. The children's education could also be progressing. He considered this method a wonderful advance in the therapeutics of spastic paralysis.

Dr. Walter G. Stern said that whatever operation might be done the athetosis would return after a while. Even if the arm were amputated below the shoulder the shoulder would move.

Dr. Allison, closing, said that they had varied the strength of the alcohol to a certain extent. It must be at least 50 per cent., and they had used straight alcohol. Some cases had a more lasting paralysis than others, and Dr. Allison thought that the percentage of alcohol might have something to do with this.

Further Observation on the Operative Treatment of Paralytic Talipes of the Calcaneus Type.—Dr. Royal Whitman described his operation, which he said was the only one that is a direct remedy for the deformity, as well as the disability. Although most effective in proportion to the relative degree of deformity, it might be used with advantage in early cases and in other types of deformity. Removal of the astragalus was the key to the operation.

Dr. Gibney said that he had always been struck with the utility of the limb after this operation. The patients walked well, and it was seldom that after long intervals they had to wear any apparatus at all.

Dr. Henry Ling Taylor did not know of any operation that gave better results in a weak foot, in properly selected cases.

Dr. E. H. Bradford said that in the hospital with which he was connected they had tried all methods for the correction of this condition. They had performed Dr. Whitman's operation in the best manner they could, though perhaps not in a manner to meet with his approval.

Operative Treatment of Deltoid Paralysis.—Dr. E. H. Bradford discussed the various methods of treatment of deltoid paralysis, and enumerated the advantages of periosteal insertion over muscle to muscle insertion. He then considered the limitations of trapezium transference, and concluded with the histories of six cases upon which he had operated by his method.

Dr. Philip Hoffmann, opening the discussion, asked what was Dr. Bradford's strong objection to arthrodesis, stating that he had had a case of this kind in which some forward and backward motion of the shoulder was retained.

Dr. David Silver asked whether in the case that Dr. Bradford had followed for ten years there was any deformity in the neck.

Dr. Whitman said that he would not expect so much as Dr. Bradford from this operation, although he had obtained a great improvement in the function of the shoulder.

Dr. Bradford, closing, said that the advantage of his operation was that free motion could be obtained, which was not possible after arthrodesis. He was in favor of preserving as much motion as possible in the joint. There was no deformity of the neck evident in his case. The reason that he expected so much was that in surgery one expects the impossible.

The Indications for and the Uses of Vaccine Therapy in Orthopedic Diseases.—Dr. Charles F. Painter, after a careful discussion of the subject, concluded that there was no well-established theoretical ground for the belief that in gonorrheal and tuberculous joint infections vaccine could play a curative rôle. Very little progress had been made as regards either the diagnosis or treatment of chronic nontubercular infections. The complement binding reaction in the diagnosis of syphilitic bone and joint infections had stood the test of practical experience very well. There was reason for thinking that the future treatment of these conditions would be much facilitated by vaccine and serum therapy, although the results of this were not yet even comparable to those obtained from the use of Marmorek's serum in the treatment of tuberculous arthritis. The efforts of the members of the association should be directed to the perfection of methods of putting into practice a test for which there seemed to be so much theoretical and experimental justification; but statistics, however favorable, would be undesirable, unless there was indisputable ground for the claim that the results recorded could be obtained under no other form of treatment.

Tuberculin in the Treatment of Tuberculous Joint Disease.—Dr. John Ridlon gave the details of these investigations, which were first by Wright's opsonic method, and later by the so-called clinical method. His conclusions were that tuberculin administered by the clin-

ical method in harmless doses was useless; and that in larger doses it was dangerous.

Dr. Gibney said that he wished to present an optimistic report on the subject. During the past winter his staff at the hospital had used streptococcus and staphylococcus serum in tuberculous sinuses, but had not used tuberculin. In six of these cases the sinuses got perfectly well, but he quite agreed with Dr. Ridlon that thee patients would improve under almost any form of treatment at first.

Dr. Young said that very good results had been obtained in Philadelphia in the treatment of sinuses with serums made from whatever germs were found present in the case. He considered it important to use the autogenous method and the opsonic index, and not to employ the clinical method.

Dr. Albert H. Freiberg said that tuberculin was merely a means of calling forth in the body the production of an increased amount of toxin, and not the toxin of the tubercle bacilli. In order to cure tuberculosis by the vaccine method, it would be necessary to use the toxin of the tubercle bacillus. At the same time, he thought that tuberculin was not getting a fair test, because bovine, and not human tuberculin, should be employed in cases of joint tuberculosis. He considered Marmorek's serum very efficient but it was hard to get and expensive.

Dr. Clarence L. Starr said that in Toronto no good results had been obtained from the use of tuberculin in joint or sinus cases. He considered the opsonic index absolutely valueless, as in children it often varied from autointoxication. He had used staphylococcus serum, and occasionally streptococcus, in mixed infections, and had obtained sufficiently good results to warrant a continuance of the treatment. It did not seem to make any difference in the result whether indifferent or autogenous vaccine was employed. He was inclined to be skeptical regarding the frequency of bovine tuberculosis in joint lesions, as he thought that these cases differed materially from human infections.

Dr. S. J. Hunkin thought that the results obtained from the use of vaccines in the treatment of bone tuberculosis were purely dependent upon the temperament of the person employing them.

Dr. Painter, closing, said that he had purposely refrained from saying anything about mixed infections, but that he believed that the only satisfactory results had been obtained in that sort of cases.

Further Observations on the Pathology of Joint Tuberculosis, and Practical Deductions Therefrom.—Dr. Leonard W. Ely read this paper (see page 147).

Dr. Young said that the occurrence of two diseases, syphilis and tuberculosis, in the same person was of interest, because he had seen tuberculosis in individuals that had previously had syphilis.

Dr. N. M. Shaffer wanted to know whether the initial lesion was in the synovial membrane or in the bone marrow.

Dr. Fred H. Albee thought that it was unnecessary to remove all the infective material in the knee joint, in order to obtain good results.

Dr. Wallace Blanchard said that he had been surprised at the number of cases of old resection of the hip joint that had come to him with a history of having been healed for two or three years. He very much questioned whether excision of the hip joint modified the progress of the disease, except temporarily. It more than quadrupled the deformity.

Dr. Davis wished to know whether Dr. Ely would at once resort to resection when he had made a diagnosis of synovial tuberculosis in an adult. Dr. Davis understood that the resection performed by Dr. Ely was merely an arthrodesis in which the cartilage was removed to secure immobility.

Dr. Ely, closing, said that Dr. Young had not understood him aright. He had thought that the case was one of syphilis, and then that it was osteomyelitis, but it turned out to be tuberculosis. He stated that it was equally common for the disease to start in the synovia and in the marrow. When it started in one it might not involve the other, but it usually did so before long. He could not diagnose the synovial from the bony type, though he could make a fairly good guess in regard to this point. He thought that the synovial disease was characterized by much less atrophy, milder symptoms, less tendency to deformity, and a slower course. When he had made a diagnosis of synovial tuberculosis, he would recommend that the joint be put up in plaster for six months, owing to the possibility of an erroneous diagnosis, and would tell the patient that at the end of that time he would probably have to resect the joint.

Osteochondritis Dissecans.—Drs. Albert H. Freiberg and Paul G. Woolley stated that Koenig had maintained the existence of osteochondritis as a distinct entity and as the cause of joint mice, excepting those produced by arthritis deformans. They reported a case in which operation and pathological investigation furnished corroboration of Koenig's views, but in which certain new aspects were added. The great interest in their case lay in the fact that three varieties of joint changes were found going on in one joint at the same time, apparently depending in their reciprocal relation upon the vascular changes. The authors did not think that the types of chronic deforming joint affections could be looked upon as separate and distinct diseases. They believed that the future would disclose the etiological factors that determine the prevalence of this or that type in a given case.

Dr. Painter did not think that the *x*-rays exhibited were suggestive of the appearances in the ordinary cases of chronic hypertrophic osteoarthritis, but said that they might have been the result of the vascular changes that were present at the same time.

Dr. Woolley said that he did not think that they had proved anything by the small amount of work that they had done, but he did believe that they had some basis for supporting the work of Wollenberg. It was interesting that in this one case they had found changes that appeared like those described by other men in various forms of atrophic and hypertrophic joint disease.

Dr. Freiberg said that he had not meant to convey the impression that these appearances were like those usually seen in radiograms of hypertrophic arthritis. The interesting point was that they had a case in which free bodies of one kind had formed and apparently were still forming, and in which a second kind of free bodies had apparently formed on other occasions. When they came to examine the changed synovial membrane of these joints, they found chronic changes in accordance with the changes described by Wollenberg in cases that were typical of hypertrophic arthritis. It seemed to the authors that these two things must be brought into correlation, and that some explanation of this character was to be found for these cases in the osteochondritis dissecans of Koenig.

Syphilis of the Bones, and Its Bearing Upon Hypertrophy and Atrophy.—Dr. S. L. McCurdy stated that syphilis was a factor in the majority of cases of bone disease of all varieties. The growth of the bone and its regeneration after destruction, as well as hypertrophies and atrophies, were considered by the author, who suggested a reclassification, with the causative factor as the basis, rather than the pathological end. He stated that in tuberculosis of the bones the bones are always atrophied, while in syphilitic bone disease they are always hypertrophied and also eburnated, with exostoses. There is always a spindle enlargement, and not only a hyperostosis, but an endostosis. He thought that Charcot's disease was

in many instances syphilitic, because it melted away under constitutional treatment. Sabre tibia he considered to be always syphilitic. The objects of operation in syphilitic bone disease are to liberate pus, to relieve pain, and to remove sequestra. One should excise, but never destroy tissue. He approved of the use of iodide of potash, but not of mercurial enunctions, and thought that mechanical treatment should be employed just as in ordinary tubercular bone disease.

Dr. Leonard W. Ely thought that syphilitic joint disease in cases of tuberculosis might exist, but that it was comparatively rare. Neither did he consider the therapeutic test decisive. He also considered the statement that the lesions of tuberculosis are always atrophic to be an error.

Dr. McCurdy had not expected that many would agree with him, but thought that the statistics that he had compiled were sufficient to warrant him in continuing his plan of treatment. When he had used iodide of potash he had usually cut short the course of the disease.

Coxa Vara.—Dr. Wallace Blanchard reported two cases of sadly deforming coxa vara, giving the histories and showing skiagrams. He thought that these cases might help to clear up some questions of differential diagnosis. He objected to the statement that coxa vara is due to tuberculosis, as he had found rhachitic coxa vara greatly in excess of all other types. This might, however, have been due to his special line of work, the correction of knock-knees. Treatment of the deformity during its progress he considered very unsatisfactory; but when the disease has run its course osteotomy for the elevation of the head of the femur and for the relief of the adduction deformity gives good results.

Dr. Davis suggested that possibly Dr. Blanchard's first case might have been analogous to cases of subluxation of the wrist, in which the wrist becomes distorted, especially the lower end of the radius. This disease occurs in adolescents and young adults, and is probably due to rickets.

Report of Five Cases of Fracture Dislocation of the Shoulder.—Dr. A. R. Shands said that the literature on this subject was very meager. His cases all occurred during the first five months of 1909, and three of them within one week and in nearly the same community. The operation on one of these cases was the most difficult that he had ever performed. He said that if he should ever have a similar case he would make an incision through the axilla, so as to enable him to do a quicker and better operation, with more ease.

Dr. J. D. Griffith asked what the condition of the deltoid was after this incision had been made, and how Dr. Shands escaped dividing the posterior circumflex nerve.

Dr. Davis said that in some operations that he had done either from the axilla or along the anterior edge of the deltoid, the exposure was not satisfactory. For this reason he subsequently used a transverse incision, running from the anterior edge of the deltoid and skirting the acromion. By this means the blood and nerve supply were not injured, and he secured a first-rate access. If the incisions are made through the fibers of the deltoid, the deltoid will be paralyzed.

Dr. Shands remarked that although his incision was not like that of Dr. Davis, he was glad to hear the description of Dr. Davis's operation. In his own operation the muscle was practically not cut at all.

Juxtaepiphyseal Fractures of the Hip and Shoulder.—Dr. Fred H. Albee discussed the diagnosis and the frequency of occurrence of juxtaepiphyseal fracture of the upper end of the humerus and femur, and said that faulty diagnoses were frequent. He took into consideration the different elements displacing the fragments, and laid stress upon the importance of the use of position in fixing the long, or controllable, fragment in alignment with the short, or uncontrollable, fragment. Several illustrative cases were cited.

Dr. H. Winnett Orr said that he had used the sort of dressing described by Dr. Albee, but had taken the liberty of extending it a short distance farther, so as to include the hand.

Dr. Frank R. Peckham said that it was important that it should be recognized that these fractures should be treated by an orthopedist, rather than by a general surgeon. He did not think that putting the limb in extreme abduction would give perfect apposition of the fragments in every case of fracture of the neck of the femur. He thought that Dr. Albee had demonstrated the application of the same principle to fracture of the upper extremity as to fracture of the lower extremity, and believed that the x-ray should be used to find out what the position is both before and after the limb had been set. Passive motion and massage should be employed early, thus causing union and the functional result to go hand in hand.

Dr. S. J. Hunkin said that his experience had shown that the fragments could not always be held in opposition in a position of extreme abduction, and he had also found it difficult in some cases to tell whether the fragments were in apposition or not, even by means of the x-ray. He thought that one should cut down upon practically all fragments of the femur, and use the finger and the eye to find out whether they are replaced. They should then be fastened with some metallic suture, and a splint allowing one to see the part should be applied.

Dr. Albee, closing, did not think that this position would hold a fracture of the neck as well as an epiphyseal fracture, although it would usually hold a fracture of the neck.

Relaxation of the Annular Ligament of the Ankle-Joint as a Cause for Weak and Flat Foot.—Dr. J. Torrence Rugh had for some years been impressed with the notion that the cause of weak and flat feet lay in the lower portion of the annular ligament, which performs three distinct functions in the economy of the foot. It binds down the tendons of the tibialis anticus and the extensor proprius hallucis and keeps them tense; it acts as a sling for the support of the dorsalis, and it takes up the slack in the plantar fascia, when the tibialis anticus and the dorsal flexor of the great toe contract. It, therefore, not only has important functions of its own, but it also assists the neighboring structures in the performance of their functions; and if they become relaxed, the strain upon this portion of the ligament increases and it may give way. For this reason it should be considered in cases of weak or flat foot.

Osteophytes of the Os Calcis.—Dr. J. D. Griffith contended that bacteria were not necessary to the production of a deposit of bone by the periosteum, but that constant irritation and pressure could easily inaugurate a locus minoris resistaniæ and strain as a cause of osteoblastic deposition, especially when perverted metabolism was added. This thickened condition or deposition of extra bone was frequently the cause of painful feet. He considered the horseshoe incision the only one that was entirely satisfactory and devoid of the possibility of causing future trouble.

An Operation for the Relief of Anterior Metatarsalgia, Including Morton's Disease.—Dr. A. Mackenzie Forbes said that this condition was primarily due to abnormal laxity of the ligaments and the transverse metatarsus muscle, allowing the falling of one or more metatarsal heads. The pressure of the displaced bone on the soft tissues beneath it was the cause of the pain, which might later become exaggerated by the formation of a callus on the weight-bearing skin. Secondarily, a mild form of arthritis would sometimes supervene. As the second, third, and fourth metatarso-phalangeal joints are

supplied by the external branches of the anterior tibial, which motor nerve supplies the extensor longus digitorum, spasm of this muscle would often result, causing hyperextension of the phalanges of the affected joints. When chronic, this hyperextension was often followed by a dorsal subluxation of the phalanx, and this tended to depress the heads of the affected metatarsals against the adjacent soft tissues. Dr. Forbes said that the only difficulties in the operation that he proposed for the relief of this condition were those connected with the attachment of the extensor tendon to the depressed heads and the guarding against a low form of infection, which might destroy the attachment. The first difficulty was overcome by raising the head by direct pressure from below.

Problems in the Treatment of Club Foot.—Dr. W. G. Stern said that when not due to faulty technique in applying the plaster cast, a decubitus occurring on the dorsum of the foot was due to cutting off of the arterial supply of the arch afflicted, and that the cyanosis of the toes was due to a damming back of the venous return. Both of these untoward occurrences were caused by the compression of the soft tissues of the dorsum from over-correction. Relief of this condition could be brought about by reducing the over-correction and fixing the foot in a less extreme position. The amount of correction practicable at any one sitting was primarily dependent upon the circulation and was often considerably less than the maximum. For the best results in club foot a maximum over-correction must be secured, but this should not be done at one sitting. The circulation in this, as in other forcible operations, should control the amount of correction obtainable at any one sitting; and if the latter was not sufficient for a permanent cure the correction must be repeated at suitable intervals until the maximum over-correction could be safely maintained.

Flat Foot, Midtarsal Valgus.—Dr. E. H. Bradford stated that the foot changes shape under different static conditions, and referred to the difficulty in checking the inward sag and twist. He then described the action of the muscles in flat foot, and mentioned the essentials of the treatment for this condition. In order to regain suppleness and strength, daily exercise was a necessity. He laid stress upon the importance of measures to correct joint stiffening and restore muscular strength. He considered supports beneficial, but not curative.

Dr. H. P. H. Galloway had used Dr. Griffith's incision with more satisfaction than he had experienced when he had used the simple linear incision. He never employed the latter on the center of the heel. He considered the operation described by Dr. Forbes to be an exceedingly ingenious adaptation of an operation employed by all orthopedic surgeons for some other conditions. He had frequently transplanted the extensor tendons of the toes in order to overcome the closed condition of the toes met with in static paralysis, and to secure more power of dorsal flexion. He then exhibited an instrument intended to center the drill in making holes in bones of small diameter. He said that he had always succeeded in relieving metatarsalgia by mechanical means. Should he find any case that he could not relieve in this way he would adopt Dr. Forbes's operation.

Dr. Davis called attention to resection of the head of the metatarsal bone for the relief of metatarsalgia and said that Morton had not infrequently found that this operation destroyed the stability of the toe. Later, Morton often performed amputation of the toe for this condition. Dr. Davis wished to know whether in Dr. Forbes's procedure the tendon of the extensor brevis would be sufficient to maintain the toe in a straight line.

Dr. McCurdy described a method of taking from the toes tendons that would be long enough to wrap around the foot in cases of closed toe, the tendons being brought back and sutured to themselves. This operation gave a perfect stable anchorage.

Dr. Young said that he had performed the Morton operation several times and had always been obliged to remove the toe. Although the statement that it is not necessary to operate on these cases had been made, Dr. Young thought that some of these cases require operation. He considered Morton's operation perfectly satisfactory.

Dr. Rugh said that he had had a patient with chronic appendicitis and with referred pain about the sacroiliac joint and down the sciatic nerve. When he had operated for the appendicitis there was no further pain in the metatarsal. We cannot always ascribe pain in one part of the body to trouble in that particular region.

A number of other papers, including candidates' theses, were read but not discussed. All the papers whose titles were on the program, if not read, were considered as having been read by title.

Officers.—The following officers were elected—*President,* Dr. Albert H. Freiberg of Cincinnati; *First Vice-President,* Dr. A. P. Shands of Washington; *Second Vice-President,* Dr. Robert B. Osgood of Boston; *Treasurer,* Dr. Gwylym G. Davis of Philadelphia; *Secretary,* Dr Ralph R. Fitch of Rochester, N. Y.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held May 9, 1910.

Dr. Charles N. Dowd in the Chair.

An Intravesico-Ureterorenal Tumor.—Dr. W. H. Luckett presented this patient and the specimen. There was nothing in the history of the patient that pointed to a tumor of the bladder, ureter, or kidney. She had been suffering from vague nervous symptoms for the last fifteen years. This was diagnosed as neurasthenia by the different internists who had seen her for the past two years. She had seen some pus in her urine, but no blood. During the last six months the patient herself had felt the tumor in the region of the left kidney. Cystoscopic examination of the bladder was made. The right ureter was catheterized and clear urine obtained. The left ureter could not be catheterized. A finger-shaped tumor apparently attached to the orifice of the left ureter extending transversely across the bladder was movable except at its attachment. Pus was seen escaping from the left ureter. Nephrectomy of the left kidney was performed. Upon inspection of the pedicle a large dilated ureter was seen plugged with a solid fibrous material. This was grasped and traction made upwards when a long worm-like fibrous tumor was delivered upwards through the kidney wound via the ureter. The lower end of this worm-like mass was recognized as that finger-shaped tumor seen at the cystoscopy in the bladder. The patient made an uneventful recovery. Two weeks after the operation cystoscopic examination of the bladder showed the absence of the finger-like tumor from the left ureter seen at the first cystoscopy. The kidney specimen was excised through the pelvis, and a large multilocular fibrocystic mass easily delivered from the pelvis and enormously dilated calyces which it was occupying. This mass was not apparently attached to the kidney, ureter, or bladder. The pelvis and dilated calyces were smooth and intact. The character of the tumor was not definitely established. Dr. Sondern was of the opinion that during embryonic life some part of the medulla of the future kidney failed to unite with the cortical portion, and as a result an inclusion has been formed which developed into the structure found occupying the bladder, the ureteral canal, pelvis of the kidney and cystic cavities of the cortex of the kidney. It was an unique specimen. The medical literature did not record a case of tumor of

the bladder being removed through a nephrectomy wound via the ureter.

Complete Avulsion of the Scalp.—Dr. J. J. Moorhead presented a woman, twenty-two years old, whose hair caught in a revolving belt and she was completely scalped in very much the same way Indians would have done it. The scalp could not be replaced because of the dirt. When admitted to the Harlem Hospital her head was completely denuded of hair. She was in very poor physical state and, therefore, it was impossible to do anything for her at first. Her hemoglobin count was down to 23 per cent. at one time. The accident happened on October 8, 1909, and on March 27 the scalp was in condition to graft. Twenty-five small pieces of skin were taken from the patient's thigh and grafted. Four series of grafts were taken, altogether one hundred and three pieces of skin. The last operation was done May 22. She developed melancholia and was transferred to Bellevue Hospital. No further operative procedure was carried out. The parts had all cicatrized except one small area the size of a twenty-five cent piece, and another the size of a dime. The grafts were covered by rubber tissue which was fenestrated and laid on as shingles on a roof.

Two Cases of Tuberculous Adenitis of the Neck Treated by Sea Air and Tuberculin.—Dr. W. M. Brickner and Dr. Neuhof presented these cases. They were two of a small series of cases of surgical tuberculosis among children of the tenements whom they had had under close observation for over a year, and whom they had treated solely by diet, tuberculin, such hygiene as they were able to secure, and, during the summer, by a sojourn at the ocean in the Rockaway Park Sanatorium for children. They illustrated nothing perhaps, except that an improvement that was at first most gratifying did not prove permanent, and that the plan had not effected a cure. Two other cases of the series were tuberculous synovitis of the knee: One, a boy, seemed to be entirely cured; the other, a girl, a case of much longer standing, was considerably improved but seemed to make no progress beyond a certain point. In the case of the boy, a high shoe, plaster casts, and crutches were part of the treatment.

Case I.—This patient came to the dispensary on March 28, 1909. Her parents, brothers and sisters were healthy. Five months before she had a swelling below the left jaw and along the sternomastoid, which developed to the size of a small pear. Three months before it had been incised in front of the sternomastoid and a large amount of pus evacuated. A second fistula developed later behind the sternomastoid; both were discharging a slight amount of turbid fluid. The general condition of the girl was fair. There was a mass the size of a walnut in the submaxillary region; the tonsils were moderately enlarged and smooth but no crypts were seen. On March 20 she was given a tuberculin injection B. E. 1/20,000 of a milligram. Injections were given semi-weekly, and diet and fresh air were advised. By May 15 all the sinuses had healed and there were no swellings visible. There were a few small glands on both sides of the neck, but the skin was everywhere movable. In June she had an intercurrent malaria, but at no time a reaction above 100 degrees. On June 28 she was admitted to Rockaway Park Sanatorium. Her weight at this time was 57 pounds. She was put on forced diet and slept outdoors. They continued to give her quinine and tuberculin emulsion up to 1/30 of a milligram. On August 15 she left the sanatorium, had gained fourteen and one-half pounds, and looked well. During this time she often had a temperature of 100° even when tuberculin was omitted. On September 27 the tuberculin was resumed, beginning B. E. 1/40,000 of a milligram. In December she had an intercurrent acute tonsillitis and submaxillary adenitis. By February 10, 1910, she was taking B. E. 5 milligrams. At that time a glandular abscess formed at the site of one of the scars which was allowed to rupture spontaneously. On March 16 she had a small superficial sinus and a slight discharge. She had frequent headaches and felt feverish.

Case II.—This boy, eleven years of age, came to the dispensary on March 20, 1909. The father had a chronic cough, but the other children and the mother were healthy. The boy had one large submaxillary gland and two smaller ones behind the angle of the jaw on the right side. There was a discharging wound over one of these which had been discharging since the incision of an abscess four months before. There were two scrofuloderma in front of these. There was dacryocystitis dextra for one month. The patient had a rhinitis with superficial ulcerations of the left nares. The tonsils were large and there was mucus in the pharynx. The lungs, bones, and joints were negative. There was an old perforation of the left ear drum. He was put on iodide of iron and syrup of hypophosphates. On March 23 he was injected with the tuberculin 1/4,000 of a milligram. This was continued twice weekly until May 1, when he was given B. F. 1/200 of a milligram. On April 24 the glandular swelling was punctured and evacuated. After May 1 he was given the tuberculin and by June 22 he took a milligram. At that time the glandular infiltration was almost gone. When he was admitted to the sanatorium the sinuses were almost closed and he weighted 61 pounds. He was kept in the open air on forced diet, etc. On September 7, after being in the sanatorium for ten weks he weighed 65½ pounds and was receiving B. E. 1/10 of a milligram. On September 29 treatment was resumed. At that time he had a gland about the size of a chestnut in the submaxillary region and a slight infiltration around the posterior scar. On November 26 there was a painful glandular swelling below the lowest scar. This subsided, but recurred again in February, 1910. The treatment was continued and now he again has glandular swelling and the right tonsil was pushed forward.

Treatment of Tuberculous Glands of the Neck. Six Hundred and Forty-nine Cases.—Dr. E. S. Judd of Rochester, Minn., read this paper. He said there was approximately 800 glands in the entire body and nearly 300 of these lay within the tissues of the neck. The glands in this region were the first to appear in the embryo. Placed at the juncture of the head and neck were several groups of glands forming a kind of glandular collar which was composed of a suboccipital group, a mastoid group, parotid glands, submaxillary glands, submental glands, and retropharyngeal glands. This glandular collar drained the entire scalp, skin, and mucous membrane of the head. There were no lymphatic vessels passing upward or communicating at any point within the skull. From the histories of their cases of tuberculous glands, they found that in 80 per cent. the first enlargement was beneath the upper end of the sternomastoid muscle, while in 18 per cent. it was in the submaxillary, submental, or parotid regions. If a routine examination was made of a great number of children between the ages of four and ten years, they would find in them varying degrees of enlargement of the glands: the changes in these glands, formerly called scrofulous, were in part simple hyperplasia, in part tuberculosis. There was no differential diagnostic criterion of the initial stage of gland tuberculosis. The tissues in these glands predisposed and invited tuberculous infection. Most of the patients upon whom they had done a complete excision of the glands had been over fifteen years of age; 18 in 649 cases were under ten years. In the presence of a discharging sinus, it did not appear advisable to excise the glands; they had usually curetted and treated by swabbing with equal parts of tincture of iodine and carbolic acid. As soon as the sinus healed, a radical operation could safely be done if necessary. Pulmonary invasion

was not necessarily a contraindication to operation upon tuberculous glands of the neck. The chief objection to the radical operation was the resulting scar. If one followed the natural creases in the neck and kept the incision as nearly as possible transverse, as suggested by Dr. Dowd, very little scar or deformity resulted. To prevent the formation of a wide ugly scar it was very essential that they turn back the platysma muscle and the skin in each flap. It was their custom to drain these cases through a stab incision. The spinal accessory nerve was the only superficial structure that it was necessary to avoid in operating. During the past fifteen years they had performed 668 operations for complete excision of glands of the neck. The following table showed the work done and results: Total number of cases operated upon, 649; total number of operations, 750; average age, 25; number of cases under ten years of age, 18; complete excision, 668; curetted, 62; both sides operated upon, 94; recurrence in region of former operation, 56 (8.6 per cent.); died of pulmonary tuberculosis, 19 (5 per cent.). Mortality, 19; one died in four weeks, one in three months, four in one year, five in two years, two in three years, two in four years, one in five years, two in six years, and one in eight years. Died of tuberculous lesions other than pulmonary, 9; died of other troubles, 14. Number of patients with pulmonary tuberculosis at time of operation, 10. In operating upon these cases it had been their effort to do a radical and thorough excision of the groups involved. Charts were shown to demonstrate the method of operating. In their series of cases they had had no mortality due directly to the operation. One patient died a few weeks after operation of general tuberculosis, and a second died in about three months from diffuse sepsis.

The Relation of the Tonsil to Tuberculous Adenitis.—Dr. F. S. Matthews said that the fact that the tonsil could be entirely removed without serious consequence to the individual was neither an argument for nor against the usefulness of the normal tonsil. There could be no doubt that germs invaded the tonsil, perhaps showing their first effects in other parts of the body. The tubercle bacillus had been found in it and had been shown to have passed through it at times without producing lesions. What they wished to know at present was, were the tonsils uniformly, occasionally, or usually a source of tuberculous adenitis. Wood of Philadelphia stated that the tonsils of persons dying of consumption showed evidences of tuberculosis in the vast majority of the cases, though other parts of the nose, mouth, and pharynx did not. On the other hand, consumptives frequently suffered from tuberculous adenitis. The tonsils of children had been frequently stated to have been tuberculous in 5 to 10 per cent. of the cases examined. On the other hand, Hodenpyl examined several hundred tonsils without finding any tuberculous ones. Dr. Matthews gave the results of the examination of the tonsils of sixty children. Over fifty of these were whole tonsils, but embraced every variety as regards size, shape, depression, and elevation. Not one of these fifty-five tonsils showed any evidence of tuberculosis. The tonsils of four patients suffering from tuberculosis of the glands of the neck were examined and each showed evidences of tuberculosis in the tonsil. He closed his paper with a brief outline of these cases.

The Treatment of Cervical Tuberculous Adenitis at the Sea Breeze Hospital.—Dr. Leonard W. Ely said that they had the histories of thirteen cases treated at the hospital under diagnosis of adenitis; besides these, enlargement of the lymph nodes had been observed in many of their patients suffering from tuberculous joint disease. The diagnosis had almost invariably been a clinical one and the treatment had been in most instances conservative. The results had been for the most part good. It was found that, as a rule, treatment was of little avail until the tonsils and adenoids were removed. About one year ago they discarded the operation of tonsillotomy and since then removed the tonsils entire. The benefits of the operation was often apparent in the subsidence of the nodular swellings in the neck. It seemed probable that if the original source of infection was removed, the nodes would subside spontaneously; but that if this be left, other lymph nodes would become involved from it. Dr. Ely then gave a synopsis of the histories of several of the cases. They considered that a great measure of their success in the treatment was due to the scrupulous care bestowed upon the teeth of the children. The dentist visited the hospital daily. Each child had his own tooth brush.

Preservation of the Submaxillary Branch of the Facial Nerve in Neck Operations.—Dr. C. E. Farr gave a lantern slide demonstration of these parts.

Dr. George E. Brewer said that they had had a large number of these cases to treat, and he confessed that he always approached the operation with dread because so frequently paralysis followed, or else some of the gland was left behind and recurrences appeared. With more experience and with more thorough operating the problem would become simpler. One should go to work deliberately and do a complete operation, removing the enlarged gland in one piece, but looking out with great care not to injure the nerves; then the results would be very satisfactory. The nerve that should be avoided lay one finger's breadth below the angle of the jaw, that was, about one-half an inch was about its usual position, but one should be prepared to meet it at a lower position. Paralysis sometimes occurred merely from traction upon the upper flap. He recalled a case in Roosevelt Hospital in which there resulted a marked paralysis and, at Dr. Weir's suggestion, to overcome the deformity he made a subcutaneous division of the nerve on the opposite side. This was followed by a marked correction of the deformity. When there was a paralysis of both muscles, there was an inconsiderable deformity. In some cases after five or six months such paralysis almost entirely disappeared.

Dr. Robert T. Morris said that the more thorough the operation the simpler it became. The matter of suturing the platysma myoides was very important in order to overcome the mechanical tendency to pull the scar apart. In addition to the stab drain Dr. Morris advocated the employment of a single layer of gauze over which he poured collodion; this caused traction along the suture line and might be retained for two or four weeks. This was done to avoid the large scars. Dr. Judd made no mention of the use of the *x*-ray in the treatment of tuberculous cervical lymph nodes. Dr. Morris said he had used with success the method of applying a bag of hot water to the affected region for two or three minutes, then the ice-bag, then the hot-water bag, etc. This he repeated every fifteen or twenty minutes or an hour morning and night. In two cases he obtained a cure after two months of such treatment.

Dr. Charles H. Peck said that these cases formed a very large group of the cases that the surgeon met. One of the difficulties encountered was the avoidance of the spinal accessory nerve, especially in those extensive cases with a diffuse periadenitis that were met with so often. It was very important that the platysma myoides should be brought carefully together and sutured before the wound was closed. He thought that the presentation of the results in such a large series of cases was an exceedingly valuable contribution.

Dr. Walter M. Brickner said that he believed surgeons were becoming more conservative in tuberculous cervical adenitis, especially when the smaller groups they saw so frequently were under consideration. He was quite sure that they saw fewer records on hospital cards of the removal of tuberculous glands of the neck now than they

saw ten years ago. Several years ago these cases were so often sent away from home to die; such cases now recovered under no other treatment than outdoor life in the mountains. He recalled one case of a tuberculous hip, with a profusely discharging sinus, that recovered after a sojourn in Maine. It would seem, therefore, that the climatic treatment of these cases was a very valuable aid, especially in the treatment of tuberculous cervical lymph nodes. Among the cases that he had had an opportunity of observing there were many that responded to conservative treatment, dietetic, and climatic, together with the administration of iodides, especially of iron. Just where to draw the line between the surgical treatment and the conservative treatment of these cases, when there was a single localized focus for instance, was a question that needed to be debated. The value of tuberculin had not been determined; when used with climatic treatment, it seemed, however, to work wonders. However, when these patients returned to their homes in the tenements, they would relapse and would be not much, if any, better than before treatment was undertaken. Dr. Brickner believed that these patients did better in the mountains where there was a dry and hard soil than they did at the sea shore.

A PRELIMINARY REPORT ON EHRLICH-HATA PREPARATION FOR THE CURE OF SYPHILIS.

By M. S. KAKELS, M. D.,

NEW YORK.

ADJUNCT SURGEON TO THE LEBANON HOSPITAL

In the latter part of August I received from abroad a number of tubes of Ehrlich-Hata preparation, No. 606, for trial on luetic patients. From the brilliant reports and successes published in the German literature one cannot dispute the specific virtues of this new remedy. In order to give this preparation a fair test I determined to use it only on such tertiary or malignant cases that had not yielded to any previous treatment. My first patient I injected on September 4, 1910, my second on September 7, 1910. Up to to-day (September 15) the results thus far obtained have been beyond expectation. The time elapsed from the injection to the publication of this report is too short to offer it as a complete observation of the results and final effect of the remedy, but the rapid and astonishing changes that have already taken place fully warrant me in offering these brief histories for publication as a preliminary report and at the same time to confirm the brilliant reports which the German clinicians have recorded. The further details and results of these cases and others will be fully published in a later article after sufficient time has elapsed to warrant us in expressing an unbiased opinion of the efficacy of this epoch-making discovery. The remedy is being used according to the strict instructions of Professor Ehrlich. It is only injected in syphilitic patients, free from other organic lesions, either of the liver, kidney, heart or circulatory system. The eyes are examined in every instance for optic nerve lesions. It is also only injected in patients who are under hospital surveillance where accurate records can be taken.

Case I.—H. S., 24 years of age, single, occupation painter, was admitted to the Lebanon Hospital in the service of Dr. Roth on August 11, 1910. Since August 8th he had acute pain in the region of the gall-bladder. The onset was sudden and accompanied by chilly sensations. No jaundice. Physical examination was negative except for a large mass in the gall-bladder region which seemed to communicate with an enlarged liver. The right border of the mass extended to a vertical line situated through a point four inches from the umbilicus. The left border of the mass ran into the lower edge of the liver which was found to be two inches below the xyphoid cartilage. From the costal margin to the lower edge of the tumor the growth measured 4 inches; its width was 2½ inches. The spleen was enlarged and readily palpable.

The patient acquired an inital sore in March, 1907, and was treated by different physicians until June, 1907. From June, 1907, for three years he was given hypodermic injections of mercury.

After his acute symptoms had subsided Dr. Roth made an exploratory laparotomy and found that the tumor mass was a gumma and was inoperable. The large liver was infiltrated with gummatous masses. The pathological report of a section of the tumor confirmed the operative diagnosis. The wound had almost entirely healed when Dr. Roth kindly turned the patient over to me for the injection of the Ehrlich preparation. A Wassermann reaction a day before the injection was strongly positive. On September 4, 0.3 grm. of Ehrlich-Hata 606 was injected subcutaneously under the scapula according to Michaelis' method. Twenty-four hours after the injection there was already a marked diminution in the intensity of Wassermann's reaction. There were no local symptoms at the site of injection although a very slight pain was experienced which disappeared at the end of a few days.

There was a slight rise of temperature (100.8°) on the ninth day. On September 5 there was a leucocytosis of 10200. There was no change in his general condition following the injection. His appetite improved. The small ulcer at the site of the incision which had not entirely healed when he received his injection was entirely healed on the second day thereafter. On the 9th of September, five days after the injection, there already was perceptible by palpation and percussion a marked diminution in the size of the tumor. The liver also was as markedly diminished in size and the spleen also. There are no changes in his eye and he is gaining in weight. The third day after the injection there was well-marked evidence of still further diminution in the intensity of Wassermann reaction.

On the 14th of September the tumor had diminished fully an inch in circumference and the liver very markedly retracted from the abdominal wall and markedly decreased in size. The spleen was also smaller. There was a leucocytosis of 9200, his urine is negative and his weight has increased five pounds in nine days. He has been examined by several of the visiting staff, as well as by other physicians who were invited to examine him, and all agreed to the remarkable rapidity with which the growth is decreasing. I have never seen a pathological mass melt away so rapidly.

The second case is still more remarkable and I can only state, in short, that Ehrlich's remedy in this instance was life-saving. Not only was the patient's life saved, but he is being rapidly restored to health.

Case II.—Henry P., age 36, bartender by occupation, acquired an initial sore in June, 1907, followed by a papular eruption. In September, 1907,

there appeared deep sores on the neck and flexor surface of his extremities which healed after three months, leaving scars which are still visible. In December, 1907, he was deeply jaundiced, had an enlarged liver and was rapidly losing weight. He had pain in swallowing. There were plaques on his tongue. The epiglottis infiltrated and swollen. In rapid succession ulcerations appeared on the soft palate, tonsil, epiglottis and glottis so that the patient could swallow liquids only after the application of an anesthetic had been made. He had sleepless nights on account of the pain and accumulation of mucus. Although slight improvement set in there still persisted lesions on the skin and mucus membrane of a destructive nature. In June and July of 1909 there were relapses of the ulcers of the larynx and marked destructive changes in the epiglottis. There was a gumma in the nasopharynx, the left wing of the nose being gradually destroyed by an ulcerative process. There were ulcerative sores on the lips, with marked destruction of the tissues.

About the middle of August, 1909, the patient was admitted to the German Hospital. He left the hospital in October, 1909, very little improved. During all this time he received the most active antisyphilitic treatment. On September 5, I admitted him to the Lebanon Hospital from the German Hospital, which he had re-entered in November, 1909, and where he had remained until he came under my care for the injection of Ehrlich-Hata preparation.

His condition at this time was pitiable. For weeks he had been bed-ridden on account of a large and deep ulcer over the left external malleolus which measured 2 x 3 inches, the result of a gumma which had existed for over eight weeks and then had broken down. There was another soft gumma on the instep with the overlying skin reddened and ready to break down. On the upper third of the left tibia there was a hard and painful gummatous infiltration. On the lower portion of his face there existed a large number of old and recent cicatrices. The lips and nose were distorted by excavations. A number of small and deep ulcers of a punched-out appearance were visible on the cheeks, nose and lips, all covered with a nasty and yellowish discharge. A large defect about the size of a five-cent piece on the right side of the nose near the tip, the result of a broken-down gumma, was still covered with broken-down tissue. None of these sores showed the least tendency to granulation. Especially the large ulcer on his malleolus was absolutely pale and indolent looking and still in a breaking-down state.

Dr. Bullinger, who had treated the patient before he entered the German Hospital, and who kindly referred him to me with the kind permission of Dr. Klotz, the visiting dermatologist to the German Hospital, had used the inunction treatment several times. He also gave hyperdermics of mercury, enesol, and atoxyl in larger doses than are generally prescribed. He also received injections of arsacetin. From time to time during these various methods of treatment periods of slight but evanescent improvement were apparent. The patient quickly relapsed into his deplorable condition. Iodide of potassium was also given. Sulphur baths were taken in Mt. Clemens, but with no other result than that he was advised to return home by the physician in charge who expected him to die in a few weeks.

In the above-described condition the patient entered the Lebanon Hospital. Besides these ulcerative and rapidly destructive lesions the patient had mucous patches in his mouth and ulcers on his tonsils which prevented him from eating or swallowing. He was despondent and depressed and in such a desperate condition that he had to be watched the first night he was in the hospital for fear he would commit suicide. His temperature on admittance was 99°, his leucocytosis 8200, the urine had a very faint trace of albumin, his weight was 101 pounds. He was unable to walk on account of the pain and large ulcer on the foot. His other organs were normal. Dr. Denig, the ophthalmologist to the German Hospital, and Dr. Heller, adjunct-ophthalmologist to the Lebanon Hospital, kindly examined the eyes, and found a cloudiness, evidence of syphilitic neuritis. The Wassermann reaction before injection was strongly positive. I injected him with the kind assistance of Dr. Bullinger, on September 7th, with 0.3 grms. of Ehrlich's preparation subcutaneously in the subscapular region. The large infiltrated area was massaged and cold applications were ordered to be made.

The patient experienced but little pain, although a very large swelling developed and persisted for some time. Temperature on the second day, 100.6°. The intensity of Wassermann reaction twenty-four hours after the injection was markedly diminished. Leucocytosis twenty-four hours after injection, 18,400. Already on the second day a marked improvement in the many ulcerative processes was apparent. The nasty discharge had subsided, a drying up of the ulcers was taking place. There was no more breaking down of tissues. Granulations were commencing to appear. The patches in his mouth and on his tonsil were disappearing. The patient could swallow, was more cheerful and his appetite was better. In fact, a remarkable change had taken place which was observed by all who examined him.

All these improvements rapidly continued so that on the 14th day of September, one week after the injection, an astonishing difference in the condition of the patient is apparent. The ulcerations and pustules have disappeared and are nearly all healed and covered by scabs. The broken-down gumma on his nose is filled up with healthy granulations and healthy epidermis is already growing over the defect. The large and deep and undermined ulcer over the malleolus is filled to the surface with active and health granulations and commencing to epidermize. His face is clean, he is able to walk, the pains have left him, the gumma on his tibia has almost entirely disappeared, the soft one on his instep almost entirely absorbed. He is not ashamed to walk about the wards. He is more cheerful and happy and has a new lease of life. He has been examined by many physicians who have seen him before and after the injection, and all expressed astonishment at the rapid improvement, and this after only one week's time and but one injection of 0.3 grm. Surely a marvelous result.

Ehrlich-Hata 606 has not only saved this patient's life, for he was gradually failing, but in a week's time has stayed the active destructive processes caused by the *Treponema pallidum*, and is rapidly restoring him to health. What remedy in the whole domain of the pharmacopœia can accomplish this?

Mankind truly is indebted to Prof. Paul Ehrlich, and owes him a great measure of gratitude.

71 East Sixty-sixth Street.

A NEW METHOD OF TREATMENT FOR CHRONIC INTESTINAL PUTREFACTIONS BY MEANS OF RECTAL INSTILLATIONS OF AUTOGENOUS BACTERIA AND STRAINS OF HUMAN BACILLUS COLI COMMUNIS.

By ANTHONY BASSLER, M.D.,
NEW YORK.

THERE is no doubt that states of chronic intestinal putrefactions are the most numerous of all medical disorders in man. Etiologically the long-established condition is responsible for more permanent types of change of the highly specialized internal organs than all other factors put together, and it is more than probable that future years will show that many of the diseases classed to-day as of obscure origin will be understood to be directly or indirectly due to states of chronic toxemia from the intestinal canal. At the present moment it is evident that many cases of the following are of intestinal origin in their establishment; chronic myocarditis; essential asthma; chronic nephritis; chronic hepatitis; chronic cholangititis, cholecystitis, cholelithiasis; chronic gastric and intestinal atonies; chronic low secretory and motor conditions of the stomach and intestine, and excess sensory conditions of the first; the mysterious peritoneal and omental adhesions; chronic constipation of dynamic and atrophic origin; chronic colitis, from the simple catarrhal to the membranous and atrophic forms; chronic intestinal indigestion, with fat, sugar, and starch intolerance; arteriocapillary fibrosis, chronic hypertension without sclerosis; premature senility; pseudopernicious anemia, and the true types following gastrointestinal atrophy; chronic simple anemias; gout, intractable neurasthenia; habitual headache; insomnia; catarrhal affections (particularly the general forms with atrophy of the submucous tissues); backache; debility; neuralgias; loss of sexual power; loss of weight and strength; mental confusions; excessive emotional depression and irritability; muscular and mental fatigue; semi-invalidism; vasomotor disturbances; degenerative states of the central and peripheral nervous tissues; functional eye conditions; hypertrophy of the lymphatic tissues; atypical rheumatism, myalgia, and particularly arthritis deformans.

The history of medicine for the treatment of those conditions shows no notable advances until quite recently, when Metchnikoff entered the bacteriology of the subject from a practical standpoint. Before that time a positive excess of indican in the urine established the case as logically one for administration of one of the new intestinal disinfectants or antiseptics (none of which ever were of any practical value) and a few items of general medicine as these seemed to be indicated. Along these lines most of the milder forms of cases improved on the general means of clinical medicine employed, and, caught by the fatus of the literature of the moment on some one of the just advanced intestinal antiseptics, the therapeutic benefits were attributed to it, and so the controversy for and against the various synthetic proprietary products continued. To-day the care of these cases is about as follows: Following the diagnosis (made mostly from the urine examination), an initial purge is given and the bowels are kept open by some constantly employed drug or enemata, a diet is installed (usually the Bulgarian bacillus milk given, and later on with it also the simple foods), and such general means employed as clinical medicine would suggest.

It is a well-known fact that an individual on a milk diet harbors fewer bacteria in the colon than one on a mixed, a carbohydrate, or a meat diet. The benefits that come from the use of the Metchnikoff milk come from the large amount of lactic acid imbibed, which assists in gastric proteolysis (the normal hydrochloric acid is usually absent or low in the stomachs of these cases) and the milk *per se* taken—not from any practical degree of antagonism between the Bulgarian lactic bacillus with the harmful forms in the intestine. While to a degree this bacterial antagonism is possible of demonstration by laboratory methods, with the results in human beings it is different. Of late I have seen some markedly advanced cases of chronic intestinal putrefaction in individuals who for weeks before had been on this form of milk made according to Metchinkoff's direction, each of whom showed no local or general improvement, the stools from whom yielded from 47 to 83 per cent. of dried weight of bacteria, with a marked preformed sulphate output in the urine, and more than an 8 per cent. loss of milk constituents in the stools.

My interest in the use of a direct bacterial method of treatment was suggested by the uniformity of the different bacterial pictures seen in examining specimens of normal and abnormal stools stained by the Gram differential method; the fact that the *Coli bacilli* grow only for a certain time in bouillon, when, probably because of their generation of thermostabile and thermolabile substances allied to phenol, their proliferation is inhibited and they become quiescent or resting but not killed (the latter was a confirmation of Conradi and Krupjurveit observations with the *Baccillus coli communis* and the *Bacillus lactis ærogenas* (the last of which organism probably suggested the use of the Bulgarian form as a germicidal bacteria against all others); and also, the fact that *Coli bacillus* were most numerous in stools of normal individuals, but were diminished or absent in most cases of excessive chronic intestinal putrefaction, having excess of indican in the urine, even when the intestinal contents have somewhat rapidly passed through the colon. About that time I chanced to read Tissier's Thèse de Paris, 1900, in which he mentioned the inhibitory action of the *Bacillus bifidus* upon the putrefactive anerobes, the latter being the predominant organisms found in these cases (these are mainly the *B. acrogenes capsulatus* and usually also the Gram negative diplococcus). Shortly following that (1907) Harter's book on bacterial infections of the digestive tract was advanced and in it the various facts pertaining to the germicidal action of the *B. coli* group were compiled, particularly in the following passages, "Nevertheless the evidence now available suggests that in health the colon bacillus, both in man and higher mammals, exerts an important function in combating the development of the injurious saprophytes with which even in health the human intestinal tract almost necessarily abound. "The presence in the colon of immense numbers of obligate microörganisms of the *B. coli* type may be an important defense of the organism in the sense that they hinder the development of that putrefactive decomposition which, if prolonged, is so injurious to the organism as a whole." "These

bacilli are essential to the life of the individual mammal as a defence against bacterial foes which it is impracticable to exclude wholly from the digestive tract, and not as agents in directly facilitating the processes of digestion in the narrow sense." At about this time I confirmed the observation of Herter that the colon bacillus has practically no power to cleave native proteins, that its peptonizing action is slight, and that alone it has not the power to cleave the peptones (and cause the generation of volatile acids, indol, and hydrogen sulphide) unless these have been prepared by peptonization by the other microorganisms. Feeling that the common picture of low amounts of Gram negative bacteria might represent a lowering of the *B. coli* instead of the *B. lactosus acrogenes,* I grew colonies of the stool bacteria from normal and abnormal stools in different media and under different methods, and observed that the abnormal stools generally showed a content of less *B. coli* than the normal stools did. After these observations I perused the literature upon the subject of the *B. coli* by different authors and noted that most of the modern standard works on bacteriology claimed that an immunity against the *B. coli* was not difficult to develop in animals. (Löffler and Abel easily immunized dogs by progressively using subcutaneous doses of live bacteria grown in solid culture and suspended in water; the blood of the immunized animal possessing an active bactericidal effect upon the colon bacteria, but the serum was not in the correct sense antitoxic.)

Opposed to the above suggestions were many facts arguing against the value of the use of installations of the *Bacillus coli communis* in such cases. The main ones were that a few cases of indolic putrefaction showed larger amount of *B. coli* in the stools than the normal amounts; the fact that the *B. coli* is capable of giving rise to large amounts of indol and indolacetic acid and a rise in the ethereal sulphates in the urine when injected into the duodenum of the dog; the statements of Herter that "muscle fiber or peptones in the lower ileum or large intestine would be attacked by the anaerobes and colon bacilli with a production of indol and subsequent development of indicanuria," and that under conditions of stagnation in the lower part of the ileum where the colon bacilli are numerous "it is not necessary for anaerobes to take part in the attack on the already hydrolyzed protein, since, as repeatedly stated, the colon bacillus itself suffices to do this" (putrefaction), which he proved by experimentation on a healthy dog, and contends is proven by an imperfect action of a cathartic in some persons causing a sudden increase of indican in the urine due to the quick passage of native proteins and peptones from the small into the large intestine where it is possible for the colon bacilli to attack the former; and further in the statement "If the colon bacilli have for any reason ascended in large numbers above their usual upper limit, namely the ileum, into the jejunum or duodenum, they will act there upon peptones formed in the course of the normal digestion of proteins and make indol, and in these instances the aid of the putrefactive anaerobes is not necessary for the production of indol," claiming also that if there had been no ascent of the *B. coli* to these regions of the small intestine the putrefactive organisms located there could cleave the proteins and then when the contents had come through the ileocecal valve the *B. coli* in the large gut would cause an abnormal production of indol; and lastly, the significance he gives to the colon bacilli in the production of the indolic form of chronic excessive putrefaction in these words—"the first may be called the indolic type, and is characterized by indicanuria dependent chiefly upon excessive decomposition induced through the cooperation of members of the *B. coli* group."

From the above statements there seemed to be certain arguments in favor and certain ones against use of the rectal instillations of autogenous bacteria and those of the *B. coli* group in the treatment of the conditions under consideration. Nevertheless, encouraged or emboldened by the results recently reported from injections of killed autogenous bacteria in the treatment of other bacterial conditions (notably in the use of the *B. coli* in bacteriuria) I instituted experiments with rectal instillations in a case which had resisted all methods of treatment for months.

The woman was one who showed large amounts of ethereal sulphates in the urine, almost Gram positive stools in which the colon bacilli were few, the stool having an acid reaction in the beginning, the patient displaying a marked anemia, debility, loss of weight, and an established neurasthenia, together with other related symptoms. For the purpose of comparison the medical treatments that had been established before were not changed during the time of injections, and the diet detailed below was continued all of the time, since it seemed a logical one for such conditions, had been established four months before, and had been closely followed.

From the onset the number of bacteria grown and injected were examined and counted in two groups (Gram negative and Gram positive), and each subsequent stool was also examined before new cultures were inoculated to note any difference in the bacterial picture as time went on. I wish to report this case in full because with certain minor exceptions it answers for the others I have treated since then with the injections of both kinds, and also because the full clinical and laboratory detail of all of the cases would be too long.

Mrs. R. E., married, age 38, born in Russia, the mother of 4 children, had measles 20 years ago. She had no illness until 3 years ago, when she began with pains in the region of the sigmoid (she was pregnant at the time). After the birth of the child she became weak and weaned the infant at the third month. Following this the weakness progressed, she became pale, and was hardly able to attend to her household duties. About a year ago she became unable to do even the lightest domestic work. Then she became markedly pale and nervous, and these symptoms progressed up to the present time. The bowels began to be diarrheal about 10 months ago, and when the diarrhea was severe she had vomiting spells. Often she has had as many as ten fluid movements, accompanied with pain, in one day. These attacks were intermittent. When menstruating she becomes generally worse and has nausea, marked dizziness, and vomiting. Menstruation now very watery and the flow is not steady. The diarrhea is usually worse when menstruating.

She was of an apathetic type, with pale membranes, soft and flabby tissues, normal lungs; heart, first sound weak and pulse weak with rate of 110; the abdominal walls were thin; there was slight splanchnoptosia. Blood, 3,700,000 erythrocytes. Hb. 67 per cent., leucocytes 7,750; a differential count was not made. On the second day following an Ewald meal, 90 c.c. of material

returned which looked well digested, with little mucus, free HCl 17, combined HCl 26, total HCl 43, total acidity 47; the pepsin activity was good and starch digestion was good. The feces were soft and mushy, and their reaction was distinctly acid; examination under low power was negative, excepting that many meat fibers were noted, under high power large numbers of Gram positive bacteria were noted mostly *B. aerogenes capsulatus* and diplococci, Gram negative organisms were few; a watery suspension of 1 to 10 developed 21 per cent. of gas. There was no blood. Segregation cultures showed meager growths of colon bacilli. The urine showed a large amount of indican, a trace of albumin, some hyalin casts, but no glucose. The weight was 113½ lbs.; it was 138 three years ago. Aug. 31 the stool showed large amounts of Gram positive and few Gram negative organisms. It had an acid reaction; the food particles were normal. The urine contained a large amount of indican, a trace of albumin, a few casts. 3.7 grams of sulphate in twenty-four hours; the ratio was preformed sulphates 10, conjugate 4. The treatment included sleep with the windows open, abundant outdoor exercise, a diet as described below, a morning cold sponge, tincture of nux vomica, paregoric and iron; also extract of malt. This treatment was continued for two months with no benefit. The woman was treated from the laboratory from this to the present, the following records being made: Dec. 27, 1909. Stool, soft, acid reaction, 2 slides of raw feces showing mainly aerogenous bacilli and Gram positive diplococci, but no colon bacilli. Segregation growths showed meager growths of the latter. Dec. 28. Dextrose bouillon: gas result 10 per cent.; very acid media, no indican. Injection 18 c.c. = 738,000,000 Gram positive and very few Gram negative (not more than 700). Urine this day showed marked excess of indican. Dec. 30. Stool much lighter in color than above and not so thin, slightly acid, slides showed large predominance of G. P. but the proportion of G. N. was slightly increased. B. A. C. very prominent and a large number of shorter rodded non-capsulated organisms were seen, the G. P. diplococci about as before. The B. A. C. were shorter than above and by comparison the bacteria picture of the slides was different from that of 4 days ago.

Jan. 1. Media gas result 25 per cent., no indican formed but some uroresin, reaction of media very acid. Marked change in the bacterial pictures of this bouillon from the foregoing; the G. N. bacteria were more prominent appearing in proportion almost like that seen in normal stools. The B. A. C. were shorter and narrower, and with the G. P. diplococci were not so numerous. The fields of G. N. comprised quite a number of thick clubbed bacilli, but by far more numerous are a thin bacilli which probably are the B. C. C. In a number of fields the proportion between the G. P. and G. N. organisms was about 2 of the former to 1 of the latter. Injection this day of 16 c.c. contained 830,360,000 of G. P. and 460,000,000 of G. N. Much time was spent in the counting. Patient says she is no better, but says that she has not so much cramps in the abdomen. The bowels had not been so loose, this morning's stool being "quite hard" (one month ago had firm passages for a few days). Her urine still shows much indican, but this was thought to be somewhat less than on all occasions before. Jan. 4. Feces soft and lighter in color than most specimens, reaction amphoteric. Stained specimen shows marked change in bacteria. The reds (G. N.) are more numerous than the violet (G. P.). The B. A. C. are much smaller, more detached, less numerous than in the other specimens, but still are more numerous than in normal stools although they are much shorter than seen in most. There are many quite small G. P. bacilli which looked unlike B. A. C. and around which no capsule could be discerned. The G. P. diplococci were about as found in former specimens. The G. N. were most prominent, being almost 2-3 G. N. diplococci and 1-3 G. N. bacilli. Segregation cultures showed most generous growths of B. C. C. which compared to the results noted from the first specimen of stools showed striking results in the way that the B. C. C. were now much more plentiful in the gut. The picture of this specimen of feces resembled closely the normal stool, and it may be said that if any difference existed it was that there were less G. P. organisms than are ordinarily seen. Jan. 5 Media gas 10 per cent., reaction of fluid acid. Appearance and proportion of G. P. and G. N. organisms about the same as before excepting that the G. N. were greater in number than the G. P. The B. A. C. very scant and still shorter than before. The B. C. C. were somewhat increased in numbers above what is observed in inoculations of normal stools. Injections, 15 c.c. = 120,000,000 G. P. and 165,000,000 G. N. Urine to-day shows decidedly less indican with a sulphate ratio of 10 preformed to 1.7 conjugate. Patient says she feels better which is the first time she has made this statement since coming under observation; she has pains only before defecation, and has had only one stool a day and that formed. Gained 4 lbs. since Jan. 30, two days before the bacterial injections were begun. Jan 7. Feces a rich brown color, medium consistence, reaction amphoteric, foods well digested, red and violet bacteria about evenly divided. B. A. C. normal in numbers (about 3 to a field), G. P. diplococci markedly decreased, B. C. C. plainly evident and in large numbers. Jan. 8. Media, 21 per cent. gas, growth almost level to top of media, fluid very acid, amount 22 c.c. = 1,171,500,000 violet mostly the B. A. C., and 1,405,800,000 reds of the small forms of B. C. C. and a less proportion of long narrow bacilli. Patent says she feels decidedly stronger, has had one formed stool a day and no pain and that she is not as nervous as before. Test for excess indican negative. Blood examination decidedly better and mucous membranes practically normal in color. Jan. 11. Feces rich brown in color and firm in consistence, reaction amphoteric. G. N. and G. P. about equal in numbers, B. C. C. very numerous in all of the fields. G. P. diplococci and B. A. C. apparently increased. Growth on potato showed a thick film of B. C. C. Jan. 12. Media gas result 26 per cent., very acid, fields mostly G. N. bacteria almost all of which are a short rodded bacilli and some cocci of the B. C. C. group. Fields were seen in which there were as many as 500 organisms and only several G. P. organisms. The B. A. C. apparently were still shorter and not so thick as in the beginning, they comprised practically all the G. P. although here and there was a G. P. diplococci. This specimen had the best growth of B. C. C. yet seen, they being present in great predominance and mostly in chains. Injection 19 c.c. = 3,400,000,000 G. N. and 97,000,000 G. P. Urine, indican free. Patient without subjective symptoms excepting still feeling somewhat weak physically but doing all of her

housework, including washing and ironing. Gained 3 lbs. more in weight. Patient given a week's interval of injections. Jan. 18. Stool brown color, reaction amphoteric; G. N. and G. P. about equal in numbers. Jan. 19. Media acid, good growth, mostly G. N. but a number of B. A. C. were present, gas 27 per cent. Injection 17 c.c. = 2,100,000,000 G. N. and 970,000,000 G. P. Urine indol free, patient says she had gained 2 lbs. in last 5 days, and that she feels still better and stronger than when last seen. Bowels moved twice to-day without pain, both stools being formed. One week interval of injection. Jan. 25. Stool of rich brown color, reaction amphoteric, more G. P. organisms noted than in last specimen. Jan. 26. Good bacterial growth in media, reaction acid, mostly G. N. but the G. P. were more numerous than in last few. Injection 18 c.c. = 2,900,000,000 G. N. and 1,900,000,000 G. P. Urine has a faint blue indican reaction. Patient says she feels well but had some abdominal pain yesterday and to-day. Conditions not so good as two weeks ago. Ordered to send stool in five days.

Feb. 1. Stool somewhat softer than last specimen, deep brown color, reaction amphoteric, more G. P. present, mostly bacilli but apparently they are not B. A. C. G. P. diplococci very few, G. N. not quite as prominent as before but still in excess of the G. P. Feb. 2. Gas result in media 34 per cent., fields mostly G. N. bacteria but many small sized G. P. bacilli were noted which probably were not B. A. C. and are of an unknown character, growth fair, injection 15 c.c. = 1,270,000,000 G. N. and 1,100,000,000 G. P. Woman menstruating on this day. Urine indican free. Told to send stool in four days but did not until Feb. 9. Stool normal color but possibly slightly lighter than last one, pasty consistence, reaction amphoteric, G. N. and G. P. about equal in number, the B. A. C. not prominent, the B. C. C. very much so. Feb. 10. Media gas result 37 per cent., growth poor as compared to all former ones, many short rodded G. P. bacilli as before, a few B. A. C. and a large number of G. N. spherical bodies of unknown character growing in groups, injection 17 c.c. = 890,000,000 G. P. and 790,000,000 G. N., most of which latter are B. C. C. Urine indican free this day, and woman had gained 3 lbs. more since last Saturday. Feb. 15. Stool formed and rich brown in color, reaction amphoteric, short rodded G. P. bacilli much fewer, a few B. A. C., G. N. and G. P. about equal in numbers. Feb. 16. Injection 15.5 c.c. = 2,000,000,000 G.N. and 1,500,000,000 G.P., bacterial growths apparently not so prolific as in first medias. Urine indican free, sulphate ratio preformed 10, conjugate 1. Patient says she had one formed and following this one fairly loose movement yesterday but no pain accompanying either or at other times. Patient looks very much improved compared to any time while under observation, is now active and quick in her manner, doing her work each day, and is happy and cheerful. Feb. 26 (ten days since last seen). Stool apparently normal, reaction amphoteric, G. P. and G. N. bacteria about equal in amounts. Only a few B. A. C. seen, but large numbers of B. C. C. Feb. 27. Media less acid than times before, growth fair. Injection 17 c.c. = 1,300,000,000 G. P. and 1,470,000,000 G. N. Urine indican free Bowels have moved twice a day for four days, no pain, since last seen had a headache for a few hours on two occasions. Gained 2 lbs. in past week. Weekly injections instituted, bacteria not to be counted, 10 c.c. of media and smaller portions of feces for inoculation to be employed from this on.

Mar. 6. Media growth good, injection 10 c.c. Urine indican free. Patient apparently well. Mar 13. Media growth fair, injection 10 c.c. Urine indican free. Patient gaining about 2 lbs. in a week. Mar. 21. Media growth fair, injection 10 c.c. Urine faintest trace of indican, sulphate ratio preformed 10, conjugate 1.2. Feels well. Mar. 29. Media growth good, injection 10 c.c. Urine indican free. Has gained 5¼ lbs. in past four weeks. Stool specimens are about the same in each, G. P. and G. N. organisms about equal in numbers, and the B. C. C. most numerous.

April 5. Media growth good, injection 10 c.c. Urine indican free. April 12. Media growth fair, injection 10 c.c. Urine, faint trace of indican, but uroresin reaction rather marked. April 17. Media growth good, injection 10 c.c. Urine indican free, no uroresin. Patient has gained 17½ lbs. in weight since Dec. 27 (weight now 131) and feels well. Interval of injections now two weeks. Still under observation after six weeks and well, although no injections had been given during this time.

The deductions from this case were that the instillations caused an inhibition to proliferation and a destruction of the *B. aerogenes capsulatus* and the Gram positive diplococci, and a raising to normal of the *B. coli* in the stools; a sudden change in the reaction of the stools to neutral, and a change in its color and the taking on of a firmer consistence; the stopping of the tendency to diarrhea and the establishing of single daily movements; an elimination of the excess indican in the urine, the sulphate partition ratio diminishing from the preformed 10 to 3.7 conjugate, to 10 preformed to 1 conjugate in six weeks; a most marked improvement in the anemia, general strength and weight of the patient; and lastly an almost permanency of these conditions over months of steady observation, the indican returning in slight excess when the instillations were discontinued for a time and its disappearance again when the injections were again given.

Since that time I have treated twelve cases, none of which had originally responded to the ordinary routine treatments, and all of which patients now have decidedly lessened indican output and all of whom have made substantial general improvement. Nine of these (ten all told) are still under observation, receiving only one injection every two weeks or so and they will be reported again at some subsequent time. The other two have passed from observation but both had indican free urines and were much improved in general health when last seen.

In addition to the above were seven additional cases, four of which were treated with the autogenous mixed injection in the beginning and subsequently with strains of *B. coli communis* obtained from other human beings, and three with the latter from the beginning. In the first four, all of which were treated for at least three weeks with autogenous bacteria, three showed improvement in the way of a lessened indican output and improved general condition from the autogenous mixed bacteria, but none of whom become indican free, or having near to a normal sulphate ratio. The fourth showed no beneficial change whatever from these injections and is included in the following (which makes four

all told) that were treated with strains of *B. coli communis* from the beginning.

The latter were supplied in individual cultures on agar-agar by Dr. William Park from the Health Board Laboratories, were taken originally from the stools of typhoid patients, and were marked "Mary, No. 168, No. 6, No. 171. Brown, No. 3, Mangiuer, and No. 170." The inoculated cultures were first grown for twenty-four hours to get a good surface growth and after this kept in the original tubes at the room temperature, and inoculations were made by placing small loops from each of the tubes into about 15 c.c. of dextrose-bouillon, and the seven strains were grown together for twenty-four hours in the oven at 37° C. when the entire media was injected into the rectum. These injections comprised amounts of the organisms varying in each single injection from 327 millions to 2 billions and the media growths were examined by Gram differential staining and also by growing colonies on the surface of different nutritive medias so as to note if any extraneous bacteria had become inoculated into the original tubes. Up to the time of writing no outside organisms had become mixed with the *B. coli.*

These last seven cases were all those of long standing conditions and may be classed as those that are obstinately resistant to all forms of ordinary treatment. In them other diagnoses of distinct organ affections were easy to be made. These were, chronic myocarditis in two, chronic nephritis in five, chronic hypertension and arterial sclerosis in five, marked anemia in six and questionable pernicious anemia in one, prolonged neurasthenia in six, premature senility in one, arthritis deformans in one, marked debility and loss of weight and strength in all. The test meal analyses showed that three had gastric subacidity, one an achylia, two a normal secretion and one an excess secretion. In none, however, did the *x*-ray examinations of the colon show any kinks, twists or other types of obstruction, although five of them had varying degrees of prolapse which probably was secondary to the general atony and loss of weight. All but one had habitual constipation, the exception having more or less regularly running diarrheal movements. The stools of each in the beginning showed large amounts of Gram positive organisms and very few Gram negatives, and the urines showed a very dark blue in the chloroform from presence of indican (Stokvis-Jaffe's test with hydrogen peroxide instead of the soda or calcium hyperchloride solution employed), and persistently high conjugate sulphate in the partition from 10 of the preformed to 2.5 to 8 of the conjugate.

With the above mentioned seven cases were two additional ones of like type but which showed high Gram negative stools in the first examination. In these it was believed that the *B. coli* were present in largely increased numbers, and these are not included in the report of the cases for the reasons that they were too few in number, because one had a marked coloptosis and the second an angulation of the transverse colon, and because neither had been under treatment long enough to arrive at any definite conclusions.

The four of the mentioned seven cases that had first been treated with the autogenous mixed injections showed decidedly lessened output of indican in the urine when placed on the strains of *B. coli*, and the development of more equal proportion between the Gram negatives and positives in the stools (usually after about the fifth injection of *B. coli*). But in all a point was reached at which subsequent treatments with the autogenous mixed bacteria seemed to be ineffective although in all relief of symptoms was reported during their course and the benefit in general health was substantial. At the end of the third month of treatment with the autogenous mixed bacteria each was put upon injections of the strains of *B. coli*, and in three an almost immediate further drop in the indican output was noted, the urine eventually becoming almost indican free. The fourth still running an excess but still decidedly decreased indican after the second month of the latter treatment (*in toto* this last case had five months of bacterial treatment). The other two cleaned up completely on the *B. coli*, two inside of ten weeks and the third during the fifth month. The detail of one of the first cases treated with the *B. coli* is the following:

J. W., June 15, 1909, married, age 51, buyer in department store. Had measles and scarlet fever when a child, and diphtheria at 21 years. Had always been constipated but was well and strong up to eight years ago when he contracted typhoid fever. Following this he had a persistent tenderness and pain in the right heel, corresponding to the inner tuberosity of the astragalus which was intensified on walking and deep point pressure and relieved on resting. About three years ago for no known reason to him he became nervous, which condition manifested itself as a restlessness, lack of power in concentrating his thoughts, an irregular insomnia, some loss of appetite, a more marked constipation, and a steady pain and distressed feeling in the stomach under the left costal arch which was independent of meals and the character and quantity of food. During the first year these general conditions were somewhat intermittent, they being less marked when he was away from business and in the country. In the winter of two years ago he grew gradually worse so that he was unable to attend to business for weeks at a time. In the summer he again picked up in strength and ability to work, but last winter he was unable to attend to business after about Jan. 1, 1909, and since which time he had done nothing in the business way, although he was anxious to. During these three years he had been in the hands of a number of men, and being neurasthenic and impatient hardly gave time enough for any of them to accomplish much in the way of benefit. The diagnoses made were somewhat varied, although "indicanuria" ran pretty generally through them all, and no doubt the treatments installed were good. He said that he made the most improvement in the physician's hands just before me who give him extract of malt and cascara segrada, a meat free diet, and ten drops of tincture of nux vomica at his meals. However, after about a month he failed to make further progress and although changes in the treatment were made said that he "could feel himself slipping back again."

Examination: weight 149 lbs. (weight 205 three years ago); has a pallid countenance and pale mucous membranes; muscles soft and his skin flabby; nervous, apprehensive and excitable; had a hemic blow over the base of the heart; a marked gastric spash and an enlarged stomach; fecal masses in the sigmoid and descending colon; exaggerated knee jerks; an arterial pressure of 170 m.m. Hg.; and a marked amount of indican in the urine (almost a blue black). Ewald meal (June

17) return 95 c.c.; finely subdivided starch; no blood, lactic acid, or Boas-Oppler bacilli; free HCl 0, combined HCl 11, total acidity 19; starch digestion to maltose marked. Feces (when four days on the test foods), dark color and acid reaction; muscle fibers numerous, some striated; large masses of vegetable substances; thick coating of mucus on surface of stool; typical Gram positive stool, showing many B. A. C. and G. P. diplococci, and but very few G. N. bacteria and not more than one or two G. N. bacilli to a field. Urine, 1,400 c.c. Sp. Gr. 1,021; acid; trace of albumin; indican and uroresin reaction marked; sulphates 4.2 grams, ratio sulphates 4 conjugate to 10 preformed; urea 31 grams; moderate number of hyalin and granular casts, some renal and many squamous cells and a few cylindroids. Blood, 3,100,000 erythrocytes, 6,900 leucocytes, Hb. 64 per cent.

From June 17 to Nov. 11, 1909, various treatments were employed with only fair and most times discouraging results. The agar-agar established daily movements of his bowels within the first week of treatment, and this regularity was maintained up to the present. He seemed to make the most improvement on excessive amounts of outdoor exercise (walking seven miles a day), morning rubs with a towel soaked in cold water, the diet, and tincture nux vomica 10 in liq., ferri albuminatis 100, taking two teaspoonfuls after meals in water. During these five months some improvement was noticed in his general condition; the best blood count was on September 17, when 4,100,000 erythrocytes and 7,200 leucocytes were counted and 77 per cent. of Hb. But on all occasions largely increased amounts of indican in his urine were observed (39 examinations), the albumin and casts persisting. At times when it was believed that the patient was substantially better (particularly one time when he returned from a two weeks' sojourn in the country) a total sulphate examination of the urine was made with a ratio sulphate, and even on this occasion the sulphate output was 4.1 grams and the ratio was 3.7 conjugate and 10 preformed. On one occasion the arterial tension was 135 m.m.Hg., but at all other times it was higher; about half of the times it was around the figure first mentioned and in a few instances it was above. The man continued to feel weak, look poorly, was unable to work, and he constantly complained of the gastric pain or distress. The examination of his stools on three occasions showed the acid reactions and high G.P. and very few G.N. organisms. It was believed in November that no better results in the way of controlling the excessive intestinal putrefaction were possible by medical means, and that only a fair degree of benefit was possible from medical treatments and then only when these were constantly kept up over lengths of time. Encouraged by the success in clearing a case just before with instillations of the strains of *B. coli*, but which case had discontinued observation when the urine had cleared and the stools had improved in character, I began these treatments in the case, continuing also the diet, morning rubs, long walks, and the tonics with the following results:

November 15, dextrose-bouillon, 15 c.c., good growth, no indol in media, and reaction acid, injection 374,000,000 B.C.C. November 19, media 16 c.c., good growth, acid reaction, no indol in media, injection 327,000,000 B.C.C. November 23, media 15 c.c., growth good, acid reaction, injection 395,000,000 B.C.C. Patient's urine shows less indican to-day than ever before; says he feels somewhat stronger and slept better. November 27, media 17 c.c. and reaction, growth good, injection 410,000,000 B.C.C. Patient gained 2 pounds in last twelve days. November 30, media 16 c.c., gas result 70 per cent., media acid, trace of indol, growth good, injection 405,000,000 B.C.C. Patient says he feels that he is getting better; his urine shows only the faintest trace of indican.

December 3, specimen of stool submitted to-day shows neutral reaction, about 1/3 G.N. to 2/3 G. P. bacteria and very few B.A.C. Media 14.5 c.c., acid reaction, growth fair, injection 315,000,000 B.C.C. Patient gained 3 pounds in last six days, appetite is much better, and the gastric distress has stopped. December 6, media 15 c.c., growth fair, and reaction acid, injection 270,000,000 B.C.C. Urine faint trace of indican and no uroresin. December 10, media 14 c.c., growth good, bacteria not counted. December 16, media 15 c.c., acid reaction, injection 347,000,000 B.C.C. No indican shown in urine test. Blood count 4,700,000 erythrocytes, 7,900 leucocytes, Hb. 84 per cent. Patient looks well and says he feels much better. Injection once a week. December 22, media 19 c.c., growth good, bacteria not counted. Urine indican free. December 29, media 15.5 c.c., acid reaction, growth good, injection 410,000,000 B.C.C. Has had no distress in his stomach all of this month, gained 9 pounds in weight since November 27.

January 8, media 17 c.c. and reaction marked, growth good, bacteria not counted. Urine shows a trace of indican. Yesterday had eaten rather large quantities of meat at two meals. January 15, Media 16 c.c., growth good, acid reacion, bacteria not counted. January 22, media 17 c.c., growth fair, bacteria not counted. Urine free of excess indican. January 29, media 15 c.c., growth fair, bacteria not counted. Gained 7½ pounds in a month.

February 8, stool examination: The G.N. and G.P. equal in numbers, few B.A.C. seen, reaction neutral. Media 16 c.c., bacteria not counted. Injection at 10-day intervals. February 18, media 18 c.c., acid reaction, bacteria not counted. Injection at two-week intervals.

March 4, media 17 c.c., bacteria not counted. Has gained 6 pounds since Jan. 29, and looks much improved and of good color. March 18, media 16 c.c., bacteria not counted, urine indican free. Ewald test meal 67 c.c., return F. HCl 27, combined 21, total HCl 48, total acidity 53. March 22, media 16.5 c.c., bacteria not counted. Patient has resumed his work, feeling strong and active. Urine indican and albumin free, but still has casts.

April 3, media 15 c.c., growth good, bacteria not counted. Arterial tension 125 m.m.Hg. April 16, media 17 c.c., growth good, bacteria not counted. Urine indican free. Continuing steadily at his work and nervousness gone. Says he feels as of old.

Treatments continued at time of writing excepting at three-week intervals. Patient well.

This was an ideal case of chronic intestinal putrefaction of the gut due to the G.P. anaerobes with elimination of the G.N. organisms, in which the results from the medical treatments continued over five months' time were only fair, and in which the fecal instillations of the *B. coli* obtained from other human beings gave signal results both in the general way and in the reestablishment of the proper proportions between the G.N. and G.P. organisms in the gut. As the latter was brought about, the amount of indican in the urine with the total sul-

phate output and the ratio between the preformed and conjugate sulphates became normal. The man was brought from a debilitated, anemic neurasthenic unable to work to one that appeared normal in every way. A further interesting fact was the differences in the two test meal analyses (made nine months apart) in which it appeared that the toxins from the gut depressed the digestive secretions, and that when these toxins were no longer generated in excessive amounts the stomach secretion returned to normal. The blood pressure also came down to a figure that may be considered as safely normal and has remained at these lower figures.

The diagnoses of the excessive putrefactive condition in the gut were made by noting the various general or organ conditions with an initial examination of the urine for indican. The condition suggested, a purge was given (calomel and salts or castor oil), and when the bowels had moved well, carmine or lampblack was given to demarcate the stools and the patients were placed upon the following test diet.

"The diet mentioned below is to be strictly adhered to for three or four days. The stools of the first thirty-six hours after its institution are of no value for examination. If constipation exists, the bowels are to be moved by injection at the end of the thirty-six hours. After this time, providing the bowels have moved well, the entire first stool is to be sent as soon as possible, no purges being taken in the meantime. Fresh specimens are desirable, and a covered small tin can or glass jar can be used as a container. The output of urine of twenty-four hours should accompany the specimen of stool.

"*Diet.*—Morning: Two thin slices of well-baked bread with butter liberally supplied; one pint of oatmeal gruel, made of about 1½ oz. or 40 gm. of oatmeal; ¼ oz. or 10 gm. of butter; 6 oz. or 200 gm. of milk; 8½ oz. or 300 gm. of water, and one egg (strained).

"11 A. M.: Milk, 1 pint or 500 c.c.

"Noon: A good-sized piece of steak or roast beef chopped or cut into very fine pieces (about 4 oz. or 125 gm.) and served on a slice of toast; one bowl (about 8 oz. or 250 gm.) of mashed potatoes with ¼ oz. or 10 gm. of butter.

"4 P. M.: Milk, 1 pint or 500 c.c.

"Night: Same diet as breakfast."

The specimen of urine was examined for indican and uroresin, and a sulphate partition was made, close attention being paid to the ratio between the preformed and conjugate sulphate. When the chromogens were markedly increased in the urine and the urine showed a ratio partition between the two sulphate combinations of more than 10 of the preformed to 1 of the conjugate a specimen of stool was examined. The reaction of this was taken, the color noted, examination of the surface layer made when it was formed not when it was of soft consistence, and a portion of the center was examined between slides with the low power to note the appearance of food crystals, etc. Seven and a half grams of the stool were macerated in 25 c.c. of sterile water and fermented and the gas result noted, and slides were made of portions of the interior of the stool, these being stained by the Gram differential method. In the latter, attention was paid to the character of the gross proportion of the Gram positive and Gram negative bacteria. When the latter were low, a tube closed at one end was filled with dextrose bouillon and inoculated. The bacteria grown in twenty-four hours was examined and comparison of these latter slides were made with those of the raw stool before so as to note the differences in the bacterial pictures and also if the Gram negatives had a tendency to increase in number when grown in culture. If such was the case, the autogenous mixed bacteria was employed, if not the *B. coli* medias were employed. These were grown in about 15 c.c. of dextrose bouillon for twenty-four hours at 37° C., at which time an examination was made of the bacterial result, and the organisms counted in classes of Gram positives and Gram negatives, or just the *B. coli* when these only were used. In some instances where doubt existed as to the character of the organisms, colonies were grown on potato and on bouillon gelatin. When the bacterial instillations were instituted close attention was paid to the clinical side of the case, the weight was taken regularly, the red cells counted and the Hb. estimated from time to time, differences in the examination of the stools and bacterial inoculation results from them were noted in all instances. Altogether, the observation covered an immense field of laboratory labor and observation, at times discouraging, but in the end most grateful.

The medical treatments that had been used before the instillations were begun were usually stopped, although when tonics, enemata, etc., were indicated they were utilized more or less although not as steadily as had been the case before. Outdoor exercises, regular hours of sleep, morning cold sponges and other hygienic details were kept up, and also this diet.

"General Rules.—Care should be taken that all foods are fresh and cleanly cooked and served. The mouth should be cleansed with plain warm water before and after partaking of food and when possible at other times. All raw fruits should always be peeled. Drink a glass of warmed flaxseed water before meals. Foods should not be eaten during conditions of fatigue, mental excitement or depression, and a rest after each meal is desirable. Thorough mastication of the food is important, and such foods as can be mashed on the plate should be so treated. The vegetables and cereals should be well cooked, and condiments, such as pepper, mustard, lemon, etc., are not allowed. Not much food should be eaten at any one time; smaller meals and shorter intervals are more desirable. Kefir, Kumyss, Matzoon, and peptonized milk are the only forms in which milk can be used.

"Foods allowed. Bouillon, consommé, broths, and purées. Well-cooked rice, tapioca, farina, sago, oatmeal, and hominy and served with milk, sugar, and fresh cream. Eggs in any form and not taking more than two in a day. Bread, rolls, swieback, toast, biscuits, and crackers. All foods made with gelatin, both the animal and vegetable form. If constipated take a handful of agar-agar finely cut once a day with cream. Take as much fresh butter, fresh cream, and olive oil as possible. Beef, lamb, chicken, sweetbreads, liver, etc., and fish can be eaten in small quantities once a day, providing they are fresh, roasted, or broiled, and taken in a finely comminuted form (their use in made up dishes is not allowed). All of the vegetables can be taken, but they must be cooked to softness; peas, beans, lentils are wholesome. The green vegetables and salads are also beneficial. When constipation is severe and the bowels do not move with the agar-agar a dish of stewed prunes sweetened with milk sugar instead of cane sugar should be taken

each night before retiring. Custards, egg and milk, cereal or fruit, jellies, marmalade, stewed fruits are allowable. Other foods of value are apples, pears, brown bread, rice, barley, black grapes, potatoes, carrots, asparagus, green chicory, cabbage, and spinach."

From the results achieved I have come to the following conclusions: In cases of chronic intestinal putrefaction wherein such conditions as carcinoma, colonic obstruction, abnormal organic disease of the pancreas or stomach, or gastrointestinal atrophy, etc., are not responsible for the condition, much benefit can come from raising the content of *B. coli communis* in the gut by instillation either of the autogenous mixed forms or strains from other individuals; whether this is due to a real antagonism between the toxins of the *B. coli* and the other putrefactive organisms, these toxins being existant in the cultures injected (which bacteriologists claim is slight in amount with the *B. coli*), or whether the *B. coli* so injected are directly toxic to these other bacteria I am not prepared to say. (We know that the dead as well as the living *B. coli* are very toxic.) But it is certainly true that an individual who has high Gram positive stools can by the autogenous mixed or *B. coli* instillations quickly have the running proportion between the Gram negatives and positives raised to a proportion equivalent to normal, this being due to a raising in the *B. coli* and also to a diminution in the putrefactive Gram positives as the first become more numerous. With this more equal proportion between the two types of organisms, the conjugate sulphate of the urine diminishes and the cases make substantial improvement in the general body. Whether this raising of the Gram negatives is only due to the *B. coli* or only to the *B. lactosus acrogenes* (both being antitoxic to other bacteria), or to both together, is not always possible of determination, since both are much alike in their morphology and are Gram negative in character. But the cultural methods of distinguishing these two forms from each other and the results obtained when only the *B. coli* were used in the injections incline me to believe that these disorders are due to a shortage or inactivity of the *B. coli*, and that the latter are the most powerful agents in the human alimentary canal against the development of putrefactive conditions, and, that while outside of the intestine they are destructive and pyogenic, inside of the canal they are welcome hosts. From my experiences I am led to believe that these injections are a valuable method for treating these cases, quick and effective in the great majority, and not harmful in any. It is my belief that when anatomic conditions causing stagnation exist the results from these treatments are not capable of giving such good or substantial benefit. As regards the permanency of the benefit brought about it is apparent that about half of the cases which do not respond to simple treatments clear up inside of from one to three months of this treatment, but that the other half may not remain substantially benefited even when the instillations are kept up for longer periods. These latter show relapses when the instillations have been stopped for a week or more, quickly responding again when the injections are reestablished and some eventually clear up. It is probable that in the relapsing cases some permanent anatomical mischief preventing the establishment of a normal bacterial intestinal condition is present, which is either the cause of the development of the condition in the first instance and then its prolongation, or that there is present some anatomical or permanent functional change affecting normal secretions and motility of the digestive canal in asthenic ways. All cases of putrefactive conditions should first be treated by the routine methods of treatment for those conditions (diet, hygiene, tonics, etc.) before instituting the instillations. When, however, the latter are begun, the autogenous mixed bacteria should first be used, always employing fresh specimens of stools for inoculation of the media and this treatment kept up for about four weeks before a change to the strains of *B. coli* is employed for a length of time, and when benefit had been established a return to the autogenous mixed bacteria may be used. If no benefit is noted on the *B. coli* alone the *B. lactosus acrogenes* may also be added to them, the two grown together in the single media, and these tried for a length of time. And if after these no sustained or apparent benefit is achieved then we have present some anatomic and permanent complication affecting the function of the gut, and the best we can hope for is a resort to surgery in some of the cases, or a longer interval continuation of instillations of whatever form of culture has shown the best results in that particular case.

The bacteria were all grown under identical conditions, namely, in about 15 c.c of 2 per cent. dextrose bouillon for twenty-four hours at 37° C., when the entire media was injected. This was done after an enema of normal saline solution to cleanse the lower bowel, the patient being on the left side and remaining so for 15 minutes after the instillation. The routine was one injection every fourth day until benefit was noted, and after this at longer intervals, the treatment being kept up for months if necessary.

A POSSIBLE SECOND ATTACK OF ACUTE ANTERIOR POLIOMYELITIS IN THE SAME PATIENT.*

By AUGUSTUS A. ESHNER, M.D.,

PHILADELPHIA.

The occasional epidemic character of acute anterior poliomyelitis had in the past already suggested the activity of a transmissible factor in the etiology of the disease, but it is only within the most recent times that the infectious origin of the disorder has been clearly and definitely established. Experimental investigation has demonstrated the cause to reside in a virus of ultramicroscopic and filterable character, capable of inducing typical palsies in inoculated monkeys, from whose nervous tissues in turn the virus can be obtained. Surviving animals thus infected have proven refractory to subsequent inoculation, and it is not too much to hope that the blood-serum of such animals may ultimately prove of prophylactic if not of curative value. The immunity thus induced is in accord with clinical observation, second attacks in the same individual having been observed with exceeding rarity.

In some instances what appears to have been an exacerbation or a recrudescence or a relapse of the disease has taken place within a short time after the inception of the primary attack, and exceptionally such a third outbreak has been reported. A few cases are on record in which a second attack has occurred considerably later in life. There is, however, a pretty general expression of opinion to the effect that acute anterior poliomyelitis in early life predisposes to the development of some other form

*Read before the American Neurological Association, May 4, 1910.

of disease of the spinal cord in later life. On the other hand, James Ross[1] makes the statement that "Persons who have had an attack of spinal paralysis do not indeed appear to be more liable in later life to other affections of the spinal cord than healthy persons generally"; and O. Medin[2] expresses the view that one attack of acute anterior poliomyelitis appears to confer immunity to subsequent attack, and he adds that he knows of no instance of relapse.

M. Raymond[3] reports the case of a man, 19 years old, who at the age of six months had an illness attended with convulsions, fever and left hemiplegia—and diagnosticated as essential paralysis of infancy, and at the age of 17 years presented symptoms of progressive muscular atrophy commencing in the right arm and leg.

A. Seeligmüller[4] states that individuals that have had an attack of acute anterior poliomyelitis in childhood are liable to develop progressive muscular atrophy later in life and he cites two illustrative cases.

G. Ballet and A. Dutil[5] report the case of a man, 34 years old, who from infancy had presented marked weakness in the lower extremities. From the age of 22 years he had transient paraplegia on several occasions, and at the age of 25 an attack of complete paralysis of the lower extremities of sudden onset. For three or four years there had been also weakness and wasting in the upper extremities. In a second case, in a girl, 18 years old, there had been an attack of infantile paralysis at the age of 3 years, involving the lower extremities, at the age of 11 or 12 another attack, involving the upper extremities, and at the age of 14 a third attack, again involving the lower extremities. Ballet and Dutil refer to a case reported by Caudoin,[6] occurring in a boy, 16 years old, who had an attack of poliomyelitis at the age of 17 months, involving the left lower extremity, and at the age of 16 years a febrile attack, attended with loss of power in the right lower extremity. They report a case of Pitres occurring in a man, 19 years old, who at the age of four years had an attack, attended with indigestion, fever, weakness and wasting in the lower extremities. Weakness and wasting increased and at the age of 15 or 16 progressive weakness and wasting appeared in the upper extremities. Ballet and Dutil also refer to the report by Charcot and by Vulpian of cases of progressive muscular atrophy in subjects previously affected by infantile paralysis.

W. R. Gowers[7] states that relapses in the course of poliomyelitis are very rare and occur chiefly in the form of a separate later extension of the disease. Second attacks, he says, are almost unknown—there had been but one instance in his series of 116 cases. He notes that in a few cases some other chronic affection of the spinal cord has developed when the subjects of infantile paralysis have reached adult life. He refers to the development of progressive muscular atrophy, of acute and subacute poliomyelitis and also of lateral sclerosis in adult life.

P. Marie[8] states that an individual who has had an attack of poliomyelitis in early life may subsequently develop progressive muscular atrophy.

E. v. Leyden and Goldscheider[9] state that exceptionally in the course of an attack of acute anterior poliomyelitis acute or subacute recrudescences occur, or there may be a gradual extension of the atrophic paralysis.

S. Auerbach[10] has reported the case of a child in whom two months following a febrile attack attended with paralysis of the left arm and leg a second febrile attack developed, with paralysis of the right leg.

Rudolph Neurath[11] reports the case of a boy, five years old, who at the beginning of August had an attack attended with fever, pains in the arms and legs, and difficulty in walking, lasting for five days; at the end of August a repetition of the symptoms, again lasting five days; and on October 3 a renewal of the symptoms, with the addition of weakness in the upper extremities, and death on October 5. Postmortem examination disclosed extensive degeneration of the ganglion-cells of the anterior horns throughout the spinal cord.

E. Lövegren[12] has reported the case of a boy, 16 years old, in whom, two weeks following a febrile attack attended with paralysis of the left leg, paralysis of the extensors of the right thigh developed.

H. Oppenheim[13] expresses the view that infantile palsy predisposes to the occurrence of paralytic conditions in later life, such as progressive muscular atrophy or chronic anterior poliomyelitis.

I. Wickman[14] states that at times poliomyelitis sets in in two stages, new symptoms appearing after the subsidence of the primary attack, the second attack not rarely taking the form of a relapse. He cites two cases of Medin in which, following a febrile period of three or four days, attended with paraplegia, there was an afebrile remission of five and six days respectively, after which there was a renewal of the fever, with marked aggravation and extension of the paralytic phenomena; and a case of Leegaard in which there was an interval of three weeks between the two attacks.

J. S. Risien Russell[15] makes the statement that in cases in which poliomyelitis is probably responsible for a uniform want of development in a limb, but without paralysis or especial atrophy of any one muscle, and in which all movements can be executed—as in a case of acute poliomyelitis—progressive muscular atrophy may be encountered later in life, but such a sequel is rare.

According to M. Allen Starr,[16] Geirsvold of Norway has reported a case in which nine weeks following an attack of poliomyelitis involving one leg, with apparent partial recovery, a second attack occurred involving the opposite leg. Starr also cites two cases of acute anterior poliomyelitis reported by Wickman in which recurrence took place at an interval of eight weeks in one and of three months in the other. Starr has himself observed a little boy with anterior poliomyelitis affecting the right arm in association with pseudohypertrophic paralysis involving both legs and the back.

Dr. Wharton Sinkler[17] has observed a case in which apparently two separate attacks of acute anterior poliomyelitis occurred in the same patient. In the first the right leg was involved and fairly good recovery took place, while three weeks later the left leg became involved in flaccid paralysis.

In the course of a paper dealing with an epidemic of 135 cases of acute anterior poliomyelitis occurring in Victoria H. D. Stephens[18] makes the statement that there is a family predisposition to the disease in some instances and that recurrence or recrudescence in the same child has occurred.

J. K. Friedjung[19] has reported the case of a boy 2½ years old who, at the age of 23 months, had a febrile attack attended with loss of power and muscular atrophy in the left arm and who four months later lost power in the lower extremities, the calf-muscles undergoing pseudohypertrophy.

A. Strümpell[20] states that in several cases of infantile spinal paralysis progressive muscular atrophy has developed later in life, and he expresses the view that the diseased ganglion-cells of the anterior horns of the spinal cord are incapable of keeping up with the functional demands made upon them and therefore undergo premature atrophy.

Simon Flexner and Paul A. Lewis[21] infer from the silence of the literature of epidemic poliomyelitis on the subject of immunity that a second attack of the disease is rare in the same individual, if it ever occurs. For this circumstance they propound two possible reasons: (1) one attack of the disease tends to confer enduring immunity; (2) owing to the infrequency of epidemics and the long interval between them, a child once infected passes beyond the susceptible age when again exposed. They found monkeys refractory to reinoculation for a short time following an attack of experimental poliomyelitis, and they succeeded in inducing active immunity in monkeys through employment of gradually increasing doses of active virus or of virus modified by heat and other physical and various chemical agents.

Lewellys F. Barker,[22] in discussing the immunity conferred by an attack of acute anterior poliomyelitis in human beings, states that this does not always develop quickly. In his opinion relapses, while rare, do occur, and sometimes two or more in the same individual.

Although in the case herewith reported the character of the second attack is somewhat doubtful, it yet seems of sufficient interest to be put on record. The patient was seen in the service of the late Dr. Wharton Sinkler, at the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, to whose courtesy I owe the privilege of using it. She was brought to the hospital September 7, 1891, at the age of 26 months. She had been breast-fed, and her dentition, although early, had been slow. At the age of a year she had an attack of cholera infantum, and at the age of 17 months an attack of mumps, followed by simple sore throat. On a warm day in August, 1891, when 25 months old, after an indiscretion in diet, and without antecedent traumatism, the child was seized with fever, lasting for three days, and associated with pain in the right leg and the back. There had been no vomiting and no diarrhea. On the fifth day the right lower extremity was found to be paralyzed, without apparent alteration in sensibility. The paralysis increased in severity for a week, and then it began gradually to diminish. The upper extremities, the left lower extremity, and the face were unaffected. The general nutrition was preserved, but the right lower extremity was moderately wasted. Intelligence was good and sensibility was unaffected. The gait was wobbling, the feet being held rather far apart in walking. There were no contractures and no deformity. The knee-jerk was normal on the left, enfeebled on the right. The circumference of the right leg was 7¼ inches, that of the left 7½ inches. The muscles of the right leg responded less well to faradic stimulation than did the muscles of the left leg, but there was no degenerative reaction. The patient occasionally had nocturnal enuresis, but there was no evidence of rachitis. Under treatment with massage and electricity for eight months practical recovery took place.

Eleven years after this illness, in March, 1903, a day after a fall, resulting in injury to the left shoulder and the left elbow, the patient developed weakness in both hands, more marked on the left. She had not been feeling well at this time and was "nervous," although she was attending school and had no fever or nausea or vomiting. When examined, May 4, 1903, there was found wasting of the intrinsic muscles of both hands, more marked on the left, with over-extension of the proximal phalanges of the left hand and flexion of the distal phalanges. Both arms were spare and much alike in size; each measured 7 inches in circumference. The circumference of the right forearm below the elbow was 7¼ inches, that of the left forearm 7 inches. The reflexes were preserved in both upper extremities. The dynamometer registered 44 and 55 on the right, 25 and 20 on the left. The knee-jerk was doubtful on the right and normal on the left. The patient still suffered from occasional nocturnal enuresis, and she had some slight difficulty in retaining urine by day, although at a later date this difficulty disappeared. On electric examination a doubtful reaction of degeneration was found in the small muscles of the left hand, the contracture of the extensors precluding a definite conclusion on this point. Response to faradic stimulation likewise seemed diminished. There was no electric change in either the flexors or the extensors of the forearms.

Under treatment with massage and electricity the condition of the right hand soon returned to normal, while a considerable measure of improvement took place in the left hand, the contractures disappearing entirely.

In August, 1903, the patient was found to have a pronounced lateral curvature, the lower lumbar region being convex to the right and the upper lumbar region convex to the left, and the dorsal region convex to the right; and a course of appropriate exercises was prescribed.

July 11, 1904, both hands were long and slender. The first dorsal interosseous space of the right hand was incompletely filled. The deficiency was more marked in the left hand, where also wasting of the remaining interossei became manifest on extension of the fingers. The hypothenar eminence of the left hand was reduced in size and the thenar eminence was even more so. When the hand was extended there was a tendency to over-extension at the metacarpophalangeal articulations, with slight flexion at the proximal interphalangeal articulations. There was considerable freedom of movement of the left thumb, although difficulty was experienced in stretching an octave on the piano, and the left hand could be readily flexed and extended. The circumference of each arm around the biceps was 7 inches. The measurements of the forearm were practically the same—right, 7½ inches; left, 7¼ inches, below the condyles; right, 5 inches; left, 4⅞ inches, above the wrist, but the circumference of the right hand at the level of the first metacarpophalangeal articulation was 7½ inches, and of the left hand 6⅝ inches. Around the remaining metacarpophalangeal articulations the measurement was 6½ inches on each side. The dynamometer registered 72 in the right hand, 46 in the left. A slight erratic knee-jerk could be elicited on either side, and the reflexes in the upper extremities were preserved. The small muscles of the left hand supplied by the ulnar nerve yielded degenerative electric reaction, with total loss of faradic response. There was normal response on the part of the muscles of the right hand and of those of both forearms.

There was little change when the patient was seen April 23, 1910. She was now employed as a clerk

and used the right hand with perfect facility and the left with some difficulty. The grasp of neither hand was strong, but it was especially weak on the left. The forearms measured on each side 8½ inches below the elbow, 7½ inches midway between the elbow and the wrist, and 5½ inches above the wrist. The thenar and hypothenar eminences were rather flat in both hands, though in greater degree on the left, where also the first dorsal interosseous space was partially excavated. The knee-jerk was inconstant and capricious on the right, and normal on the left.

There is no reasonable doubt that in the case reported the attack of illness at the age of 25 months was one of acute anterior poliomyelitis. Such a diagnosis is fully borne out by the mode of invasion, the symptoms and the course of the disease, and the results of treatment. Whether, however, the second disorder, at the age of 13½ years, attended with weakness and wasting in both hands, transitory on the right side and persistent on the left side, is to be attributed to peripheral nerve injury in consequence of a fall or to a second attack of poliomyelitis must remain an open question. The development of the symptoms a day following and not immediately after the accident, the involvement of both hands primarily, even though in slight degree and but transitory in character on the uninjured side, the absence of sensory alterations certainly entitle the possibility of a spinal rather than a peripheral lesion—a poliomyelitis rather than a neuritis—to serious consideration.

Conclusions.—Acute anterior poliomyelitis is an infectious disease, occurring in sporadic or epidemic distribution. It is due to an as yet unidentified virus, capable of inducing the disease in monkeys, from whom in turn the causative factor can be obtained and be transmitted to other animals. One attack confers relative immunity to subsequent infection, although it may predispose to other diseases of the spinal cord in later life. Relapses and second attacks in the same person are rare.

A BRIEF REPORT OF THREE UNUSUAL CASES OF RETROPHARYNGEAL ABSCESS.*

By ALEXANDER SPINGARN, A.M., M.D.,

Brooklyn, N. Y.

Attending Physician, Department of Diseases of Children, of the Bushwick and East Brooklyn, and of the Jewish Hospital Dispensaries.

The following three cases of suppuration in the retropharynx that I have observed during the past two years presented points of such unusual interest in the course of the disease and in the complications and sequelæ, that a brief report is apparently justified.

Case I.—Retropharyngeal abscess, associated with evidence of pressure on the pneumogastric nerve. S. B., male, age 8 years, American, of Russian-Hebrew parentage. Family history negative, except for mild attacks of rheumatism in the father. Personal history: He has had measles when three years old, scarlet fever when five years old, and has from time to time complained of pains in the lower extremities. The present illness began three days ago with malaise, anorexia, chilly sensations but no distinct rigors, and with pain and stiffness of the right side of the neck. There was at first no soreness of the throat nor pain on swallowing. When seen at the end of three days after the onset of illness, the patient presented the following: He was a boy slightly undersized for his age, and evidently underfed. He was pale, weak, and considerably prostrated. The skin was hot and dry. The head was stiffly held in the position of right-sided torticollis with the chin rotated to the left side. The right sternocleidomastoid was rigidly contracted and at the right angle of the lower jaw there was a mass of hypertrophied lymph nodes, about the size of a pigeon's egg, and exquisitely tender. Examination of the mouth revealed a highly coated tongue and a number of carious teeth. The tonsils were slightly enlarged and congested, and the mucus membrane of the pharynx was granular and congested, adenoids were present, but there was otherwise no evidence of any swelling. The thoracic and abdominal viscera presented nothing abnormal, excepting for an unusual slowness of the heart. The temperature was 103.4, the pulse 60, and respiration 20. The pulse was full, regular, and of good force, equal and synchronous in both radial arteries and synchronous with the heart beat. This extreme slowness of the pulse with a temperature of 103.2 added a perplexing problem to what would have been a provisional diagnosis of acute cervical adenitis, with torticollis, possibly of rheumatic origin. The slowness of the pulse suggested meningeal irritation or intracranial pressure. But there were no other evidences of either of the latter. The pupils were equal, of normal width, and reacted equally and normally to light and to accom-

*Read before the Pediatric Section of the Medical Society of the County of Kings, March 23, 1910.

modation. The reflexes were normal. There was no retraction of the head, nor ache cérébrale, nor retraction of the abdomen. The mentality was not dulled. A tentative diagnosis of cervical adenitis and rheumatic torticollis was made, and the salycilates were administered. During the next five days the symptoms increased in severity. The torticollis was more pronounced, the pain more intense, and the swelling at the side of the neck attained nearly the size of a hen's egg. It was hard and tender, but not red, and no point of fluctuation could be detected. On the eighth day of the disease the patient began to experience pain and difficulty on swallowing. Examination of the throat revealed a swelling of the posterior and right lateral walls of the pharynx, about one and a half inches in diameter, hard to the touch, and with no fluctuation. The temperature was now 103.6, and the pulse rate 58. A diagnosis of retropharyngeal abscess was made. The slow pulse was now easily explained on the basis of pressure of the inflammatory mass in the retropharynx upon the vagus nerve.

A vertical incision one-half inch in length was made in the center of the pharyngeal swelling, but no pus was evacuated. The suppuration was evidently deep, and had not yet come to the surface. The following day a discharge of pus came from the opening. In the course of three days the temperature subsided gradually to normal, and the pulse-rate increased to 90 per minute. The swelling subsided, and with it disappeared the torticollis and the dysphagia. On the fourteenth day of the disease the patient was entirely well, except for the inanition, weakness, and anemia resulting from the acute illness, the suppuration, and the inability to swallow. The two striking points in connection with this case are the initial torticollis and external cervical adenitis, and the remarkably slow pulse that could be explained only on the basis of pressure on the pneumogastric.

Case II.—Retropharyngeal abscess followed by general pyemia and death. The patient, C. W., was a female infant, 13 months old, of Russian-Hebrew parentage. The family history was negative. The infant had been born after a normal labor and was breast-fed. She had had no previous illness of any kind. Early in February, 1909, another child in the family had contracted scarlet fever. Quarantine had been raised during the third week in March.

Two weeks later C. W. took sick with fever, vomiting, anorexia, and restlessness. The symptoms continued and at the end of eight days the infant was unable to swallow and had retraction of the head. At this time the physician in attendance had made a diagnosis of retropharyngeal abscess. By means of his finger-nail he succeeded in incising the mass, and in evacuating a considerable amount of pus. There was a temporary and partial improvement of the symptoms. The infant was soon able to swallow, the retraction of the head was relieved, but the high temperature did not subside and the restlessness and anorexia continued.

I saw the infant one week later, April 20, 1909, obtaining above history. On that day the examination of the case showed the following: The infant was extremely pale and moderately emaciated and weighed 16 pounds. The skin was hot and dry. The inspection of the head revealed a firm mass of hypertrophied lymph nodes at the right angle of the jaw. An irregular red scar on the posterior wall of the pharnyx was the only evidence of recent retropharyngeal suppuration. The ear drums were normal. There were no signs of difficult dentition. Heart and lungs were normal. The abdomen was slightly protuberant. The reflexes were normal. The temperature was 102.8, pulse 130, respiration 24. Urine was normal. Blood showed 3,200,000 red-blood cells, and 12,000 leucocytes. The stools were green and contained a moderate amount of mucus. The infant was moaning most of the time and slept but little. No diagnosis was made. The treatment instituted was the administration of small doses of calomel, cool sponging of the surface of the body, and the application of a 5 per cent. ointment of ichthyol to the inflamed cervical lymph nodes. During the next ten days the temperature continued with slight morning remissions. On the fifth day the swelling at the side of the neck began to subside, and in two days was succeeded by an area of redness and induration over the right temporal region, about 2½ inches in diameter. Under the application of ichthyol, this area of redness and induration disappeared within the next 48 hours. The symptoms of fever, restlessness, and anorexia continued. On the tenth day the temperature rose to 104.2°, and thereafter acquired a more marked remittent type, dropping to 100° to 102° in the morning, and rising to 104° to 104.8° in the evening. The Widal reaction was negative, the spleen was not enlarged, and there were no rose-spots. There were no malarial plasmodia to be found in the blood. The Moro tuberculin reaction was negative. Repeated careful examination of the lungs revealed no signs of consolidation. There was no evidence of cardiac involvement. Repeated inspection of the ears revealed no abnormality. The infant had a decidedly septic look, but the exact locality and source of infection could not be discovered. The remissions in the temperature, which on some days ranged as high as 106, became more and more marked. On May 7, 1909, auscultation of the lungs revealed a slight diminution of the intensity of respiration over the base of the right lung behind. The percussion note was normal and there were no râles to be heard.

An aspirating needle was introduced at the ninth interspace and 1 dram of serosanguinolent fluid was withdrawn. Microscopic examination of this fluid revealed neither cellular elements nor organisms, and culture media inoculated with the fluid remained sterile. Two days later both ear drums were slightly congested but not bulging. A paracentesis of the drum membranes was performed and a small amount of thin serous liquid was discharged. The following day the discharge from both ears became purulent. The septic character of the temperature became more pronounced, reaching as high as 106.2° in the evening and dropping to 100.2° in the morning. At this time distinct rigors set in. On May 12, the right conjunctiva became reddened, the cornea clouded, and the pupil reacted sluggishly. The following day the entire eyeball was markedly injected, the cornea became opaque, and the pupil became completely immobile. Dr. James W. Ingalls confirmed the diagnosis of suppuration of the vitreous humor. The following day, May 14, 1909, the infant developed unmistakable signs of bronchopneumonia at the base of the right lung, the respiration became superficial and extremely rapid, the heart action more feeble, and on that day death occurred. Unfortunately, no au-

topsy could be obtained. The history of this case is typically that of a general pyemia following a retropharyngeal abscess, and strikingly emphasizes the importance of making a prompt diagnosis of the latter condition, and of instituting early drainage.

Case III.—Retropharyngeal abscess associated with edema of the glottis. G. W., a 14-month-old infant of German parentage, was seen December 27, 1909. Family history was negative. The infant had been born after a normal labor and had been breast-fed until it was nine months old. Her development has been normal and until the present time there has been no illness. Seven days ago the infant became peevish and restless, had a slight fever and a pronounced coryza. The next day, a swelling appeared at the right side of the neck. There was slight interference with nursing, apparently on account of the coryza. The stools were constipated. Physical examination showed a well-developed infant weighing 18 pounds. There were a well-marked coryza and a mass of hypertrophied lymph nodes at the right angle of the jaw about one and a half inches in diameter. The throat showed slightly hypertrophied but not inflamed tonsils, and the mucous membrane of the pharynx was reddened, and presented no visible swelling. The thoracic and abdominal viscera presented nothing unusual. The temperature was 102.6°, pulse 140, respiration 24.

In accordance with these symptoms, a diagnosis was made of acute coryza with cervical adenitis, and the treatment consisted in the administration of divided doses of calomel and a mild fever mixture, the use of an antiseptic nasal spray, and the application of a 5 per cent. ointment of ichthyol to the glandular swelling. The symptoms continued with no abatement for the next seven days. The temperature ranged between 102° and 102.8° from day to day. The difficulty in nursing became more marked. On the fourteenth day of the disease, the infant was brought to the clinic. It was much worse than it had been on any of the previous days. It was slightly cyanotic, extremely restless and in great distress. The respirations were considerably labored, 40 to the minute, and characterized by inspiratory and expiratory dyspnea. Examination of the throat at once revealed the cause of this condition. The right lateral wall of the pharynx was considerably swollen and edematous, and the edema extended forward to the right pillars of the fauces and to the soft palate. The uvula was pushed forward and to the left. Digital exploration of the pharynx showed that the swelling and edema extended downward and involved the structures that surrounded and included the larynx. The cause of the dyspnea was thus easily recognized and the diagnosis was made of retropharyngeal abscess or lymphadenitis, associated with edema of the glottis.

The treatment demanded prompt surgical intervention. By means of a narrow-bladed scalpel, guarded to within one-quarter of an inch of the point, a half dozen small incisions were made into different portions of the pharyngeal swelling. A small amount of pus was evacuated. Within the next six hours the edema of the laryngeal structures subsided and respiration became freer. The swelling in the pharynx disappeared in the next three days, and the infant was well within one week.

623 Willoughby Avenue.

LIBRARY VENTILATION.

By W. A. EVANS, M.S., M.D., LL.D.,

CHICAGO,

COMMISSIONER OF HEALTH, CHICAGO, ILL., PROF. OF PREVENTIVE MEDICINE, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL.

The ventilation of a library offers several problems which are a little out of the ordinary.

1. The air must be clean enough for the books and of the right humidity.

2. If there is a general reading room with newspapers it will probably be patronized by a good many people with unclean clothes and unclean bodies.

3. Books and ink have odors peculiar to themselves which are apparent where there is a good deal of massing.

4. The temperature must be that best suited for quiet, inactive people with a low heat production and a tendency toward cold feet.

5. Among the people visiting libraries there will always be an undue number of convalescents. Among them, from time to time, will be found convalescents from diphtheria, scarlet fever, and measles; also people liable to infect others with tuberculosis, pneumonia, and colds. The disease-spreaders mentioned in the first group will be found to be more numerous in schools than in libraries, while the spreaders in the second group will be found more frequently in libraries than in schools. In a circulating library books may be returned from premises where there is contagion.

6. In the stack room a good circulation of air is difficult to attain.

Beyond these points the proposition of ventilating a library does not differ from that of any other installation.

Dust. In a windy place or one where there is a good deal of atmospheric dust it is difficult to keep the books cleaned unless the air is cleaned before it is introduced into the room. Vacuum cleaning of the books and shelves has very great advantages. There is scarcely an installation in which it has greater advantages than in a library. To take each book and wipe it off with a damp cloth, then to wipe off the shelf and replace the books entails expense which is almost prohibitive. If the library ventilates by open windows they should be covered by cheesecloth fitted to the windows in frames. These cloths should be easily removable so that they can be cleaned and replaced with little expense or trouble. If the air is artificially introduced it should be washed or filtered through cheesecloth.

Humidity. If the air is too dry the books will dry out; the leather will crack and break; the glue and paste will become brittle. If the air is too moist the walls, shelves, and books are liable to "sweat" and the books be injured thereby. To prevent sweating of the books is more a matter of arrangement of the shelves than anything else. The shelves should not be against the outside walls or near the windows. To keep them off the outside walls and away from windows gives better light and throws the light so as to illuminate the shelves.

A temperature of 65° F. with a relative humidity of 65 means .289 grams of water per cubic foot of air. If, now, the temperature of a given object falls to 53° F. the dew point is reached for each particle of air in contact therewith. The amount of precipitation will depend upon the number of degrees of the air below 53° F. and the amount of

air coming in contact with the chilling point. Outside walls, dependent upon their thickness, will chill below the dew point on their inside faces. It is better to keep books away from them and on stacks on inside walls or set on the floor. If stacks must be against outside walls, enough radiation should be placed along these walls to hold their inside faces above the dew point in zero weather. In setting stacks on the floor of a room, over an unheated basement, something is gained by putting them on a wooden base or some other base composed of a poor heat conductor.

General Reading Room. The temperature must be held fairly high, say 65° F., since the occupants are still and quiet and the circulation in their feet is probably sluggish. If the humidity is low the secretions of the bodies will dry and increase in offensiveness. If the relative humidity is below 50 the occupants will be chilled if the temperature is below 70° F. If the humidity is high the body and clothes odors become doubly oppressive; witness the oppressiveness of a rainy day. It is a basic principle of the handling of odors that they must be removed just as directly as possible. The ventilation of kitchens has taught us that the only way to prevent the dissemination of odors is to place a hood over the cooking stove and remove the odors directly. The body odors of a general reading room are not so strong and do not require as vigorous treatment, but the principle is the same. The fresh air should be introduced low down at a temperature of, say, 60 to 65°, and at a low velocity. The outlets should be high up. The space occupied by the readers should have as nearly even upward ventilation currents as it is possible to get. The worst of the down draft influences should be obviated by placing radiation under the windows and next the outside walls, and in any other places where there is a tendency to downward currents of air.

If the ventilation is by gravity the air should enter the room through radiation so as to bring the air to at least 55° F. when it enters the general air supply of the room. If this is not feasible, then deflectors must be inserted in or near the window openings in cold weather so as to send the cold air to the ceiling that it may be warmed before it reaches the floor. Odors, in such an installation, cannot be controlled except by using large quantities of air. A general reading room should be so arranged that its air can be blown out at intervals during the 24 hours.

Stack Room. The stack room odors are those of large quantities of ink and paper. This room is not especially disagreeable nor harmful. Air in plenty and an occasional blowing out is all that is required.

Contagion. There are a few things in a library management or arrangement which can be done to lessen the danger of contagion. Periodic blowing out of the air of the room will do much toward keeping the bacterial content of the air low. To provide sunshine will lower the bacterial content of the air of the room. To keep the air of the room fresh will lower the danger of infection of the occupants of the rooms. To place the reading tables and chairs so that the readers will have their backs toward each other rather than facing each other across tables will decrease the danger of infection of readers in some measure, as it has reduced the consumption rate among cigarmakers. To provide convenient and commodious washing facilities will decrease infections.

Several plans are available for the disinfection of returned books in a circulating library. Exposure to the sun's rays is effective and practicable in small libraries.

As the stack room is used by but few people, good ventilation is not as necessary as in the reading room. If there are racks which are not against the wall they should be so built as to leave some clear open space under the books. Again, space should be left between the top of the books and the ceiling. If ventilation is by windows, the aisles should be so arranged as to make the best possible use of the windows. If the ventilation is artificial, the ducts should be carried under the stacks and the air introduced from under them, as the space under the seats is used in railroad car ventilation.

Something can be gained in keeping dust off the books by having the stacks made with cloth backs instead of wooden backs, in order that the air getting into the shelf space will have its dust filtered out.

PSYCHOTHERAPY—ITS PLACE—ITS USES.*

By B. C. LOVELAND, M.D.,

SYRACUSE, N. Y.

NEUROLOGIST TO THE HOSPITAL OF THE GOOD SHEPHERD AND THE FREE DISPENSARY.

Psychotherapy is a comparatively new term, but that does not signify that the method is new. Ages ago a wise man wrote "There is nothing new under the sun," but even if that be true there has grown up in the last generation quite a dictionary of new terms in electricity, and one almost as large in neurology. A fair definition of psychotherapy might be the application of the power of the mind to the cure or relief of disease.

With this in mind a little study of the history of medicine would show us that the psychic influence was used way back in the infancy of the art, as early or possibly earlier than the first recorded use of material remedies. And from what we know of primitive remedies I think it would be safe to say that the psychic was more potent for cure, and possessed of less danger, than most of the material remedies used in those early days.

In primitive times, as we all know, the practise of medicine was purely empirical, and in the hands of the priesthood. It is said that history repeats itself, and if we study history we will see that with the discovery of material remedies of real value, through the development of chemistry, pharmacy, anatomy, and the allied sciences, and the separation of the practise of medicine from priestcraft, for a time the influence of the mind for the cure of disease became eclipsed by the more tangible methods.

The natural result of this apparent neglect of such a potent influence for good in the cure of disease was first the growth of homeopathy, which avowed the existence of a spirit or influence in medicine after such dilution as to eliminate all the physical or chemical properties of the drug, and proved the ability of Nature to cure with much less medicine than was at one time thought necessary. Later, for the same reason came Christian science, whose founder was, I am informed, once an ardent advocate of homeopathy, and still later came mind cure, New Thought, and their numerous variations, and last the Emmanuel movement, which tends to restore to the clergy their primitive function of min-

*Read before the Academy of Medicine, April 5, 1910.

istering to disease. These later isms or methods, all simply excrescences on the practise of medicine, have filled many a page in our magazines of late, and cause an unusual amount of discussion.

All this means that the power of the mind over the body has been rediscovered, but the use of the remedy should be claimed and administered by that body of medical men whose only binding obligation is to use "any remedy, from any source, in any form, which experience teaches is valuable in the cure of disease or the relief of suffering."

There have been through all time occasional men in our profession who, though untutored in modern psychology, have recognized the value of mental therapeutics, and have used psychotherapy as successfully as any of its modern followers who have been so much before the public of late.

I will give an instance or two of the use of the method by one of a generation now gone which will illustrate not only the wide range of application, but the rare tact required to adapt the method to the individual peculiarity. The psychic stimulus or suggestion may be conveyed by some material remedy or instrument, or may be given direct, and may be in the form of a command, an assertion, or masterful statement, an analysis of symptoms with explanations, reinforced by illustrations, or it may be only the hidden inference that the patient draws from the appearance or actions of the physician, or the remedy he prescribes. The use of the psychic influence is unconscious to a great extent so far as the average physician is concerned, but should be studied and used with a purpose to get its best results.

The first illustration from the experience of the old physician referred to occurred about 60 years ago and was as follows: The physician came in from a drive, whip in hand, and found a nervous, dyspeptic man grumbling at his assistant because he was no better after weeks of treatment, and blaming his lack of improvement on the doctor for not giving him a proper tonic. He then appealed to the old physician who apparently agreed with him. Then, turning to the assistant, he grumbled worse than ever. "Yes," said the old physician, "I do think you need a tonic, and I will give it to you now." And with that he proceeded to apply his whip around the man's legs. At first the patient was nonplussed, then indignant, then too angry to know what to do. While he was thinking what to do to get even with the doctor he began to work at his trade, that of a carpenter, forgot his stomach, and was on the road to health. A few months later he came back so improved in appearance that the doctor did not recognize him. In this case the remedy was heroic, and the psychic was stimulated through the physical.

Another instance illustrating the pure psychic was as follows:

About twenty years ago a prominent clergyman came to this same physician, now an old man, with the pitiful, though common, story of overwork, long continued, resort to stimulants to keep up, the habit formed, and now the man discovered that he is a slave to stimulants, and likely to disgrace his profession. He seeks the old doctor, of whom he has heard for years, in search of help, and tells him his whole story. The doctor sees the need and recognizes the avenue of susceptibility. He tells the clergyman he needs Divine help, and straightway proceeds to invoke Divine aid, and the clergyman is carried along wtih him as a child might be with a father. The doctor urges his patient to make confession, and begin in public his reformed life, which he does. Now, after more than 20 years, this patient still shows the permanence of the cure.

These cases represent the two extremes of the method, but in attempting to adapt it to any given case the physician may find the avenue of susceptibility any where between, and here his knowledge of human nature, as well as his tact, is required.

I know a physician who is so confident in his belief in Nature's power to cure when hygiene is aided by psychotherapy that he practises his profession with no medicines, except a hypodermic case for emergencies, and a set of colored sugar of milk tablets for every other kind of a case, using the placebo as a vehicle with which to administer suggestions, and to secure the patient's coo-peration and obedience. Such extremes are unwise and would work ill to the profession if known. I also have known surgeons to do operations when the physical condition did not demand it, but the operation was so on the patient's mind that the surgeon thought the mental effect of the operation would warrant it. Such a use of surgery is at best, experimental, and of doubtful expediency.

It would seem that no argument should be necessary to convince one that a remedy so potent for cure in some cases and so totally useless in others should be handled only by those who by training and education, not only know the method of application of the remedy, but are also skilled in diagnosis. It would then be obvious that no one however versed in psychology should essay to apply that knowledge to the art of healing unless such person is also possessed of a sufficient knowledge of anatomy, physiology, pathology, and the other fundamentals of medical education to enable him to make a reasonably correct diagnosis, and then he could apply this or any other remedy, or combine psychotherapy with other remedies in such a way as to contribute to the greatest good of the patient. Then if it should chance that he found himself deficient in the technique of psychotherapy he would have the same opportunity to call in the services of a specialist as he would in some case which required surgery or hydrotherapy in which he might not feel qualified, or did not have the time or the conveniences at hand.

And as the physician might, at times, call to his aid the services of a trained mechanic to help him fit some orthopedic appliance, so he might call in the aid of the clergyman when he recognizes that the avenue of susceptibility in any given patient required that the suggestion be applied along religious lines with which he might not have sufficient experience to use successfully, while he himself should keep the general control of the patient.

This is sufficient to show what I consider the place for psychotherapy. The uses of psychotherapy may be such as to give it the rank of a specific in some cases, *i. e.*, a trouble existing in the mind alone must be treated by mind therapy as a specific. But whether or not it be used in the sense of a specific it is always a valuable aid to material remedies. The remarkable results one man gets with a remedy in which he has unbounded faith while most of his professional brethren get no such results can only be explained by the psychic influence he exhibits with his medicine, which may be quite wanting in the use of the same medicine by others.

The physician who gives a medicine and fails to tell his patient what to expect as a result of the

remedy may get results, but even then he will miss one-half the good which would follow if he had seasoned the dose with a proper amount of psychotherapeutic flavor. It is not difficult, and the time and energy is well spent in thus flavoring your doses. But when the case is purely psychic, and the mental remedy is the specific it is no easy matter at times to work down through the various layers of long-buried thought or experience to find the original germ idea which has grown insidiously, spreading as it grew till it has made a network through the whole mental fabric of the poor unfortunate which is absolutely paralyzing to normal mental activity. Yet before any successful suggestion can be applied this germ must be found and rooted up. In fact, if you can induce the patient to uncove this germ and produce it for discussion you have gone far toward curing him. Such morbid thoughts die when brought in contact with the light and atmosphere of a healthy intellect, as mould dies when brought from the cellar into the air and sunshine.

But this takes time, and patience, and thought, often much of all of these. Does it pay? Let us see. A young mother came into my office one day looking the very picture of despair. She had come in seven miles from the country where she lived with her husband and baby alone. On a recent trip to the city she reached the culmination of a nervous state which was partly hereditary and partly acquired, became hysterical, and thought she was going to die, or was losing her mind. A physician was called in who did what he could for her, but failed to eradicate the belief that her condition was critical. A fear of death or insanity settled down on her till she did not dare to stay alone with the baby for fear that she would lose her mental control and kill the child. This fear so distressed her that she was in despair, and said that she could not and would not go home, but she did not know what she would do. She loved her baby and she could not bear to think what might happen if she should lose her mind. After she had talked and cried herself out, by tactful persuasion, the germ of her fear was brought to the surface, discussed, and driven out. She left my office very different from the way she came, went home, and took up her work, and up to the present time the fear has not returned. She came in to see me one day within a week and gave a good report. This case was comparatively simple and easy, though a considerable time was consumed in the first visit referred to. But it took a large number of visits, and much reiteration, and repeated explanations to bring the mother back to a useful member of society, and a homemaker for her family from a condition of chronic invalidism of four years' standing. The mother's dominating ideas were very similar in character to those from which her daughter had suffered, but had been strengthened by the time they had existed which made her recovery more tedious.

More cases could be reported, and if time would permit, methods of psychodiagnosis might be discussed, but each case requires a different avenue of approach, and every man does, and probably always will, adapt for his own use more or less of a composite of the various systems, or evolves a system of his own, for making that mental analysis which is required in these cases. Enough has been said, however, to make plain the uses to which psychotherapy may be applied, and the proper persons to be entrusted with the use of the remedy.

CULTURE OF LACTIC ACID BACILLUS IN THE TREATMENT OF CHRONIC SPECIFIC URETHRITIS.

A PRELIMINARY REPORT OF THIRTY-FOUR CASES.

By G. A. PERSSON, M.D.,

MOUNT CLEMENS, MICH.

Old as the human race, the records of gonorrhea have come down to us through history and its onward march has left in its wake blind, halt, maimed, and sexless multitudes. It is to-day contributing no little to the non-efficiency of our men at the most productive age and thousands of women are directly or indirectly suffering from this infection; there is also no doubt it is a considerable, though hidden, factor in present mortality. Dr. John Van Rensselaer Hoff holds the attention of medical men by his display of recent statistics on venereal diseases, in which it is estimated that 1,500,000 men suffered from gonorrhea in the United States last year. This is a startling fact, which makes us ask with some hesitancy: As an unavoidable sequence, how many of the other sex suffer likewise? Chronic specific urethritis is a neglected but important factor in social hygiene and the physician in general medicine has a duty to perform to the large class of patients who have presumedly been cured of gonorrhea.

Not infrequently an applicant for examination will say that since the cessation of all symptoms of infection he has often had relation with women, among them several not given to sexual promiscuity. Indeed, his intimacies with one or another may have extended through prolonged periods, with the result that not one of them was infected by him. In explanation thereof, several elements may enter, among which the most frequent only can be mentioned. One woman contaminated with gonorrhea may have presented such slight manifestations of the disease that they pass unobserved or she may have been perceptibly infected but concealed her condition; again she may have had relation with another man, whom it might be more advantageous to accuse, and so on throughout the gamut of ignorance and cupidity. It would seem, however, fortunately for the human race, that a number of women, for a time at least, are immune to gonorrheal infection. A man who states that he observed the first symptoms of a gonorrhea within forty-eight hours after impure relations, is exposed to the suspicion of having there suffered a recrudescence of a preceding and perhaps forgotten infection, or to have acquired the disease in coitus within eight or ten days of the presumed cause. One in whom the first evidence of a specific urethritis appears weeks or even months after coitus may have had a similar experience or may have failed to note the first manifestation of the disease. In the latter case it may have been a "blenorrhagie chronique d'emblée," as Guiard calls what is ordinarily designated a "mild case." Parenthetically it may be observed that these so-called "mild attacks" often prove very rebellious.

Let it be assumed, for present purposes, that the patient has but one attack of gonorrhea. Let it be assumed further that for several years thereafter he observed no vestige of the disease except for the appearance of a seemingly insignificant discharge which continued a short time, disappeared, but reappeared again after long or short intervals.

The patients here reported were subjected to the following methodical examination:

Urethral Specimens for Microscopy.—The patient is ordered to present himself upon voiding his first morning urine. If any reason, such as distance of his residence or the need of early rising, prevents this, the patient is provided with sterilized, blunt toothpicks and microscopic slides and instructed in the technique of taking any excess of urethral secretion that may present. He is also provided with six clean three-ounce bottles with clean corks, and instructed to pass into them his first morning urine. He is further instructed to write his name or other distinguishing mark and the date on the labels of the bottles and to number the succession in which each bottle is used.

When the patient can come to the office before having voided his first morning urine, the urethra is stripped; should stripping fail to bring an excess of urethral secretion to the meatus, the urethra may be curretted with a sterilized platinum loop and the results finely spread on a flamed coverglass for microscopic examination. At the same time that a specimen is obtained for microscopy one or more slants of Loeffler's serum are inoculated by stabs and strokes and put into incubator at 90° F. The patient is now instructed to fill a 12-inch (180 cc.) ignition tube with his urine and entirely fill as many more tubes as he may need to almost empty his bladder. The remaining quantity is passed into a final tube. As the patient has used each tube it is immediately stoppered with sterile cotton and marked by means of a "glass pencil" with the patient's name and numbered to designate its place in the succession of tubes used. If the urines intervening between the first and last are perfectly clear and contain no "floaters," and the first and last suffice for microscopy, the intervening tubes may be discarded. The first and last tubes are sedimented and the results prepared for microscopic examination.

Specimens from Prostate and Seminal Vesicles.—If the preliminary preparation of the patient has not resulted in recrudesence of the discharge the prostate may be massaged and the seminal vesicles stripped for specimens in addition to those taken from the urethra. The contents of the adnexa mentioned as present at the meatus were used for microscopic specimens and culture. Should no secretion be immediately obtained by massage and stripping, the patient is instructed to walk about for a few moments; usually at least a slight oozing then presents itself. If this does not occur, the urine passed within five or ten minutes hereafter will be found in some instances to be loaded with the secretion that has escaped. Specimens herefrom are then available for microscopy.

Case I.—Mr. W. B., aged 25; was infected two years ago, the primary symptoms having been moderately severe. He received treatment for several months consisting of irrigation and internal medication. At no time during the period of this treatment did the symptoms entirely disappear. At present a very slight urethral discharge is noticeable only at times. The treatment consisted of urethral injections with a culture of the lactic acid bacillus once a day. All other treatments discontinued. An examination 5 and 10 days after commencing treatment showed gonococci present; on the fifteenth day there were very few gonococci; on the twentieth day their presence was doubtful; on the twenty-fifth and thirtieth days no gonococci were found, and the patient was discharged. Four months later he was again examined, but no gonococci were found.

Case II.—Mr. W. R., aged 45, married, had specific urethritis at the age of 20, from which he apparently recovered. He married at the age of 26 and three years later he was again infected; the second attack was very mild in character. Slight discharge continued for a long time, but the patient discontinued treatment and finally noticed a disappearance of all symptoms. This, however, was but temporarily, since the second infection the patient having had a periodic reappearance of urethral discharge. Examinations revealed gonococci in large numbers, and urethral injections with a culture of lactic acid bacillus were given once a day. Examinations made every five days showed between the fifth and thirtieth days that gonococci were present, whereas from the thirty-fifth to the fiftieth none were found, and at the end of this time the patient was discharged.

Case III.—Mr. F. J. has had specific urethritis three times; the last infection dates back six years. Urethral discharge has been visible at short intervals from last infection to present time. Examination revealed gonococci and staphylococci. Injections with a culture of lactic acid bacillus were made once a day. Examinations made every five days showed gonococci present until the twentieth day. From the twenty-fifth to the fortieth they were not found. After six months the patient was again examined, but no gonococci were found.

Case IV.—Mr. F. H., aged 24, had specific urethritis two years ago, since which time there has been a recurrence of the primary symptoms at intervals varying from six weeks to three months; a week previous to his first visit at my office these symptoms became very acute, the patient being unable to account for this condition, as cause for a new infection was lacking. Inflammation of the urethra was very marked and introduction of a soft rubber catheter was associated with great pain. Examination revealed large numbers of staphylococci and gonococci. Urethral injections with a culture of lactic acid bacillus were made once a day. Examinations made on the fifth, tenth, and fifteenth days showed gonococci to be present; while later examinations were negative.

Case V.—Mr. J. H. had specific urethritis three years ago, all symptoms disappeared in a comparatively short time, but he was reinfected six months ago; no physician was consulted but some proprietary preparation was obtained from a druggist and the patient treated himself. The acute symptoms were relieved in a few days but a slight discharge continued up until the present time, when gonococci were found in large number. Treatment, urethral injections with a culture of lactic acid bacillus once a day. Examinations showed gonococci present for twenty days after commencing treatment, after which time they were not found, and the patient was discharged on the thirty-fifth day.

Case VI.—Mr. T. G., aged 48, has had a slight urethral discharge at short intervals about six years, and examination revealed gonococci. Urethral injections with a culture of lactic acid bacillus were made once a day. Examinations on the fifth, tenth, and fifteenth days after commencing treatment showed gonococci to be present; on the twentieth and twenty-fifth days they were not found; on the thirtieth, thirty-fifth and fortieth days they were again present; but from the forty-fifth to the sixtieth days, when he was discharged, they were not found.

Case VII.—Mr. W. T., aged 68. This patient

was infected while serving as a soldier in the Civil War and has never been entirely free from a slight urethral discharge for longer than three or four months at a time. Examination revealed the presence of gonococci, staphylococci, and colon bacilli. Urethral injections with a culture of lactic acid bacillus were made once a day. Examinations made every five days until the sixtieth day after commencing treatment showed gonococci to be present; on the sixty-fifth and seventieth days they were doubtful, and from the seventy-fifth to the ninetieth they were not found.

Thirty-four patients have been treated by urethral injections with a culture of lactic acid bacillus, six of which received no benefit. In the remaining twenty-eight cases the specific microorganism disappeared, and all clinical symptoms subsided.

Preparation of the Culture.—A strain of the lactic acid bacillus, which coagulated milk at room temperature in twenty to twenty-four hours, was planted in the following media: Milk, 70 parts; physiological salt solution, 25 parts; nucleanic acid, 5 per cent., 5 parts, and incubated for twenty-four hours, when plate cultures in agar were made. The first colonies appeared on the agar plates in from eighteen to twenty hours; these were selected for sub-cultures in a media of: Milk, 60 parts; physiological salt solution, 33 parts; nucleanic acid, 5 per cent., 7 parts, which were grown in the incubator twenty-four hours, when again plate cultures in agar were made and the first colonies appearing were transplanted. By this method the quantity of milk was gradually decreased, the physiological salt solution and nucleanic acid correspondingly increased, until good growth was obtained in a media of 85 parts of physiological salt solution and 15 parts of 5 per cent. nucleanic acid, which culture was used as the urethral injection.

Conclusions.—Secretions present in the infected urethra inhibit the growth of a common strain of lactic acid bacillus. Suspension in physiological salt solution of lactic acid bacilli grown on slant agar was injected into the infected urethra and cultures obtained by means of a sterile platinum loop from the urethra—these cultures were planted in milk at the following intervals: First culture, one minute after injection; second culture, five minutes; third culture, ten minutes; fourth culture, fifteen minutes; fifth culture, twenty minutes; sixth culture, thirty minutes. After forty-eight hours' incubation there was complete coagulation in cultures one and two; slight coagulation in culture three; in culture four, acidity but no coagulation; in cultures five and six, no growth.

It was observed that the disappearance of the gonococci bore a constant relation to the length of time the lactic acid bacilli retained their virulence in the urethra.

In each of the six unimproved cases the bacilli were killed almost immediately after injection and although several different cultures were tried, none proved effective.

Cultures of lactic acid bacilli grown in nucleinic acid media, such as used in the treatment of the cases here reported, retain virulence when injected into the infected urethra for a much longer period of time.

In a number of instances cultures which coagulated milk in thirty-six hours have been obtained from the urethra of the patients under treatment ten hours after the injection was made.

A PLEA FOR THE STUDY OF GERIATRICS.

By I. L. NASCHER, M.D.,

NEW YORK.

The strain of sadness which permeates "De Senectute" destroys our faith in the great Roman's optimistic philosophy. Seneca, like Cicero, preached resignation, yet feared death. And so through the ages, philosophers have tried to look forward to the inevitable with the indifference of the fatalist or with the courage of the hero who approaches an unknown enemy, with the faith of the visionary who sees beyond eternal life, or with the grim resignation of despair. Yet, in spite of all the optimism of philosophers from the days of Seneca and Cicero to Jean Finot and Metchnikoff, man looks forward to death with fear and indignation. It is only when one can take a purely materialistic view of life and knows the succession of biological processes and the progressive changes which finally destroy the harmonious relations necessary to maintain the living organism intact, that one can look upon death calmly. Even then death is repulsive, for it opposes the first law of nature, the law of self-preservation, and the desire to live. The new-born infant knows nothing of death, it knows nothing of life, yet there is the instinct of self-preservation. It gasps for air, it seeks the nipple and suckles, it cries to make its wants known. As it grows older it takes an interest in life, and later it finds a pleasure in living. Still later the basic motive of the individual's efforts is found in a desire to live. There is still the fundamental instinct of self-preservation, there may be still a pleasure in living. This desire to live is apart from the instinct of self-preservation; indeed, the latter may be suppressed by force of will without impairing the desire. This desire to live persists in old age, even when there is no more pleasure in life, and when the dulled mental faculties make death less fearful. There are cases where the individual desires death or precipitates it to obtain relief from mental or physical suffering, but such cases are abnormal.

The old man has been described as a blind and pitiless egotist, jealous and suspicious, having lost all interest in everything outside of himself. The few remarkable exceptions bring out more strongly the generality of these qualities which are based upon the old man's intense desire to live. Sentiment condemns the discussion of the economic value of the decrepit old man to society at large or to the community, to his relatives and friends, or to himself. Though this be a utilitarian age, when the desirability of men and things is gauged by their practical value, we may not discuss even in the medical press subjects as euthanasia in painful, incurable diseases, the destruction of the new-born monstrosity, or the fetus to save the life of the mother, however valueless such lives may be. After the individual has entered the stage of decrepitude he has only a sentimental value to society. For all practical purposes he is not alone useless, but generally a burden to himself and family, and often to the state. Sentimental value, however, exceeds all economic value. In dealing with life, public sentiment, whether based upon humanity or sentimentality, takes unapproachable precedence, and public sentiment in civilized communities decrees that we must preserve the aged and make them comfortable. It declares that the old man is a human being, having an intense desire to live; he has served society in one capacity or another, and gratitude, as

well as humanity, demands that we prolong and ease his declining years. If we take an unimpassioned view of the position the old man holds in society we must acknowledge that notwithstanding this humane recognition of his work we show little of the altruistic spirit in our manner of dealing with him. It is hardly necessary to compare the condition of the uncared-for child with the condition of the uncared-for old man, the public asylums for children with the public asylums for the aged, nor need we dilate upon the difference in treatment in the private home where children and their grandparents entail burdens upon the family.

There are many circumstances and conditions under which the aversion to the aged is natural and excusable, under which even sympathy and sentiment are stifled. There is no occasion or condition under which the medical profession is released from its obligation to tender sympathy and to extend aid in distress to the limit of its ability, yet nowhere does the medical profession neglect its obligations to humanity so uniformly and so obtrusively as in dealing with the aged. I do not mean to say that the physician, called to an aged patient, neglects to do all in his power to relieve distress. There is no lack of individual sympathy. The profession as a whole is indifferent to the aged, since it makes no effort to study the senile state, the wants and needs of the aged, their diseases and discomforts, or to relieve them. Aside from the asylums for the aged there is not a hospital or dispensary for the treatment of senile cases, or which considers such cases apart from the ordinary cases of maturity. There is not a lecture given in any medical college, so far as I have been able to learn, upon geriatics, that branch of medicine dealing with senility and its diseases. There is not a medical society or a section of a medical society that takes it up, nor a medical journal devoted to it, although one journal (*The Medical Council*) has recently set aside a section on geriatics. There are several German and French textbooks on the subject, but I cannot find one modern American work or even an English translation of one of the standard German or French works of the present day. This is remarkable, as senility and its diseases have engaged French and German investigators for over seventy years, there is a very extensive literature upon the subject in the two languages, and, besides, from a scientific standpoint, senility offers greater and more interesting problems than childhood or maturity. There are great differences in anatomical features and physiological functions between senility and maturity than between childhood and maturity. We know how pathological processes affect the normal tissues in maturity, but we know little about the effect of pathological processes upon the degenerating senile tissues. Drugs act differently upon the aged than upon younger persons, because the tissues themselves are different and the power of absorption and assimilation are changed, yet physicians as a rule give the drugs that they give in similar diseases in maturity, perhaps diminishing the dose in a haphazard manner, without rule or system. Secondary effects upon degenerate tissues not involved in the disease are generally ignored, and patients die from these secondary effects.

We treat our senile case with the idea that while we hope he will recover we expect that he will die: and when we expect a fatal issue in a senile case we lose interest in the case and do not exert ourselves as we would in childhood to prevent it. "The old man must die, anyway; why strive to prolong his useless life?" Every physician who has given an unfavorable prognosis in a senile case has been assailed with the same question: "Why prolong the agony?" His conscience, as well as the family, repeats the same question. It is his duty to prolong the agony because it is the duty of the physician to prolong life. Aside from sentiment, humanity, sympathy, aside from every ulterior consideration, the physician's self-imposed obligation demands that he save life, even the useless life of the pain-racked, decrepit old man.

While this is the duty of the physician, the attitude of the profession is one of indifference. Few are interested in the hygiene, regimen or dietetics of old age, factors more important in senility in preserving health than in maturity. A single instance will suffice to show the importance yet general neglect of these factors. In a home for the aged many inmates began to cough every night after going to bed. During the day the blankets were folded back, allowing the linen sheets to be thoroughly aired. Before retiring the inmates closed the windows to warm the room, and spread out the blankets. The sheets remained cold, and when the old people got into bed they were chilled, while those who had bronchitis at once gave evidence of it. We all know that we cannot sleep in a cold bed until the heat from our bodies has warmed the bed sufficiently to make us comfortable. The old are naturally cold; they have a lower body temperature, there is less radiation, and it takes much longer to warm a cold bed from the body of an old person than from the warm body of a younger and more active individual. By neglecting the simple hygienic measure to warm the sheets before the old people went to bed they were compelled to endure unnecessary discomfort, to lose sleep, to suffer the pain and annoyance of coughing and disturb those who did not cough. In many other directions is the medical neglect of the aged observable. In health, the diet altered to meet the altered digestive powers, the dress, the bath, the exercise regulated by the changed anatomical and physiological conditions, mental stimulation agreeable to the mental capacity of the aged, sleep, all come within the physician's field, yet are neglected. In disease, with the sole exception of arteriosclerosis, the ailments of the aged have received but little attention in this country. Senile debility, the most obvious of the senile manifestations, causing the greatest physical discomfiture and producing a constant mental depression, does not figure in American medical literature, yet much can be done to improve this condition. The increasing mental weakness receives no consideration until it has reached the condition of senile dementia, when it is transferred to the field of the alienist. The senile tremor goes to the neurologist and the senile gangrene goes to the surgeon. The flat-foot goes to the orthopedist and the enlarged prostate goes to the genitourinary specialist, while another specialist takes care of his stomach and still another takes care of his heart. But who looks after the old man? All these ailments are due to, or part of, the normal senile changes. It is the old man, the individual, who needs the care of a specialist so that he may be free, or comparatively free, from the discomfitures of old age, and that he may avoid many of the ailments which otherwise fall later to the surgeon, the alienist, the neurologist or other specialist.

Whether we view the old man with the eyes of

the scientist who sees in him only an interesting study, or with the eyes of the humanitarian who sees here an object of sympathy, or with the eyes of a man who sees here a fellowman anxious to live, our duty as physicians is the same. We must prolong his life and relieve him of his ailments. We cannot perform this duty if we do not study his life and his ailments. Such study may reveal a difference in the properties of tissue cells at different periods of life, thus explaining the degenerative changes in senility. An intimate study of the metabolic changes at this period may explain the altered assimilation and lead to a rational scientific hygiene of old age. The study of the action of inflammatory and other pathological processes upon degenerating tissue, the action of drugs on such tissue, a knowledge of the incidental secondary diseases which destroy life in senility, are all necessary if we expect to cope with senile diseases successfully. We must look upon senility as a physiological entity as much so as is childhood, and while there is lacking the sentimental interest in the old man that there is in the child, we have here an object of greater scientific interest. From whatever standpoint we view the old man it is the physician's province to relieve his ailments and prolong his life.

The object of this paper is to arouse an interest in geriatics. With such interest aroused, we could set aside a ward in our hospitals, a class in our medical schools, a column in our journals, a section in our societies, for his benefit. It is not too much to expect that as a result of such interest we may discover the underlying causes of aging, and, minimizing the causes, defer senility and prolong life.

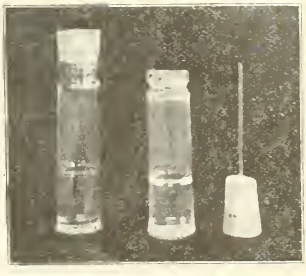
A PRACTICAL INEXPENSIVE ASEPTIC BLOOD-STICKER.

By C. C. BASS, M.D.,
NEW ORLEANS, LA.

The accompanying illustration shows a very satisfactory blood-sticker. It costs only about five or six cents and may be made up in a few minutes. It is superior to those on the market in that the needle is conveniently kept in alcohol or other antiseptic solution. This blood sticker is especially prac-



tical in laboratories where large classes are being taught blood examination. An essential part of the equipment for each such student is some kind of blood sticker, just as a stethoscope is essential for physical diagnosis students.

This sticker is made of a two dram vial, cork, and a straight surgical needle. The eye end of the needle should be stuck into the small end of the cork. The needle should not be stuck through the cork.

741 Carondelet Street.

A "Chamber of Horrors."—An anti-vivisectionist "chamber of horrors," such as was conducted in this city during the recent session of the State Legislature, has been afforded room at the State Fair now in progress in Syracuse. It is an exhibition of degeneracy—degeneracy not of the doctors whom it grotesquely slanders, but of the exhibitors. These people are afflicted with the mental disease which alienists diagnose as zoophil-psychosis, a love of pet animals that has become morbid. Women who coddle their pets and love them more than babies cannot bear the thought that dogs, cats, monkeys, and guinea pigs should be experimented upon, even painlessly, by the humane searchers after remedies and methods for the cure of human diseases. They would prefer that thousands of children should die in the horrible agonies of cerebrospinal meningitis or drag out crippled and disfigured lives from infantile paralysis to having a few hundred animals sacrificed for the sake of their cure—a cure that would work for all time. They would rather have millions of homes made charnal houses, haunted by the dread spectres of cholera, smallpox, typhoid, diphtheria, lockjaw, cancer, tuberculosis, and the Black Death, rather than that the veins of one horse or one cow be tapped for an immunizing serum, or a white rat be engrafted with diseased tissue to watch the method of proliferation and discover its preventable causes. They would construct a "chamber of horrors" full of all manner of deceitful representations to inflame prejudice in the minds of untaught beholders, while ignoring the real and terrible spectacles in the sick-chambers of the Nation. These people are working to spread plagues. Dr. Simon Flexner, who stands at the head of work in experimental medicine in this country, calls them "enemies of mankind." While a little insane, the leaders of this movement are wholly responsible for their work. The result of their campaign in the State and county fairs this Fall should be the strengthening of sentiment to restrain their degenerate exhibitions by law.—*New York Times.*

The Internal Secretion of the Pancreas.—As the result of a series of transfusion experiments, performed by anastomosing the blood-vessels of normal animals with animals in which glycosuria had been produced by means of extirpation of the pancreas, E. Hédon concludes that the internal secretion of the latter organ brings about a modification of the blood preventing glycosuria. But his experiments did not exclude the possibilities of the nervous origin of this condition. The two theories of the nervous and humoral origin of diabetes are not incompatible; it is probable that the pancreas regulates the metabolism of sugar by means of a double mechanism; a complex humoral component and a reflex nervous element related chiefly to the glycogenic function of the liver. As regards the possible rôle of the bulbomedullary centers in this mechanism, recent experiences of the author have shown that it is not a necessary one. In dogs rendered paraplegic by means of section of the cervical cord, the extirpation of the pancreas produces a diabetes as intense as ordinarily.—*Revue de Médecine.*

Use of Sterilized Clothing for Infants.—Edmond Weill advocates the use of sterilized clothing for infants as a preventive of localized skin lesions of pustular nature. The clothing should be regarded as a true condenser of germs, and the skin should be treated as a surgical wound is treated, that is with aseptic precautions. He found in the crèche at Lyons that all these local skin suppurations were prevented, and that in children who had contracted them the use of sterilized clothing soon put an end to them without other treatment. Each outfit is placed in a canvas bag and then in the sterilizer, and the bag is not opened until the clothing is to be used. After the linen so prepared had been used on one occasion the sterilizer was undergoing repairs and unsterilized clothing had to be used, with the result that the suppurations began to occur again, and stopped only when sterilized clothing was again used.—*Archives de Médecine des Enfants.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, September 24, 1910.

THE ESTIMATION OF ANAPHYLAXIS.

SINCE the discovery by Theobald Smith a few years ago of the phenomenon of anaphylaxis or fatal hypersensitiveness of an animal to a foreign serum produced by a previous injection of a similar serum, not only have the serologists devoted much time to the investigation of this obscure subject, but the clinicians have also been obliged to give it consideration in practical therapeutics, for fear that in cases of diphtheria, meningitis, septicemia, or any other of the ever-increasing list of diseases amenable to serotherapy, a repetition of the inoculation of the antitoxin during a period in which anaphylaxis is well developed might, instead of curing the patient, cause his sudden death. The subject is of especial importance in cases in which an immuning dose of antitoxin has failed to protect the subject, and the disease has made its appearance in spite thereof. In such cases the physician who blindly injects antitoxin is taking risks with his patient such as few would wittingly care to run. The great danger lies in the hidden character of the phenomenon, in the fact that we have no means of ascertaining until too late whether or not the anaphylaxis has developed.

In the hope of obtaining a practical method of testing a patient's sensitiveness to horse serum and thus of being able to tell in a particular case whether an antitoxin injection will or will not be dangerous, Knox, Moss, and Brown, at the suggestion of v. Pirquet, have carried on a series of experiments with the injection of horse serum into the skin of rabbits, and have reported their results in *The Journal of Experimental Medicine* for July, 1910. Rabbits which previously had been sensitized by the injection of horse serum in amounts varying from 0.1 c.c. to 10.0 c.c. were at definite periods given intradermal but not subcutaneous injections of very small quantities of horse serum. The results were uniform and striking. After a period in the neighborhood of ten days, during which the sensitization process occurred, an injection of even so small an amount as 0.01 c.c. of horse serum produced a definite local reaction at the point of inoculation.

The reaction is described by the authors as follows: "The bleb produced by the intradermal injection of the serum disappears in a short time, and no change is noticed at the seat of injection for ten to twelve hours. After this time the skin may become a little reddened and infiltrated, so that when it is taken up between the fingers in a fold it seems definitely thickened as compared with a fold of skin elsewhere. The swelling and redness continue to increase and reach their height in about twenty-four hours, when there may be a definitely raised brawny mass perhaps one or two centimeters in diameter. The skin of the reacting area is red and increased in temperature and the mass is definitely tender. Reactions which were less severe exhibited only a more or less diffuse infiltration of the skin at the point of inoculation with little or no redness or heat in the shaved area as compared to that of the rest of the skin. In a number of rabbits the reaction was much more marked. In these the infiltration began sooner, the part affected extending five to ten centimeters, became very tense, swollen, and red, and on several occasions partly necrotic. Reactions of this fulminating character often lasted for two or three weeks, whereas those which produced less severe changes diminished after twenty-four hours. On several occasions the reactions took the form of an unusually firm, sharply circumscribed, round mass with less increase in local temperature and redness than was usually the case." Microscopic examination of sections of the skin showed marked edema. There was little or no constitutional disturbance at the time of the reaction. Efforts to produce an antianaphylaxis failed, as did those to get the reaction in the newborn offspring of anaphylactic animals.

As this local reaction is produced by a minute quantity of horse serum, as it appeared with regularity in rabbits sensitized by previous injections and was as uniformly absent in nonsensitized animals, it would appear to be a fairly accurate indicator of the presence of a hypersensitiveness of the animal, in short to be an index of anaphylaxis. If further investigations confirm these findings and supply us with an accurate and innocuous indication of a state of hypersensitiveness in the human subject who has received a previous antitoxin injection the work will have to be accepted as an important advance in practical serotherapy.

ACROASPHYXIA IN CHILDHOOD.

THE vasomotor neuroses form a large group of disorders to which clinicians have as yet paid but scant attention. Accordingly, knowledge of the pathogenesis and symptomatology of these affections has not kept pace with the study of the physiology of the vasomotor nerves. Claude Bernard, Morat, Dastre, Gaskell, and a few others were the pioneers who cleared the ground for the pathologists and clinicians.

The prôtean manifestations of these conditions apparently account for the neglect which they have suffered at the hands of clinical investigation. That these diseases are not altogether uncommon is attested by the fact that most practitioners will readily recall familiar cases belonging to this category. The vasomotor manifestations of functional and organic nervous disease, including peripheral nerve lesions, and the less common disorders, such as

Raynaud's disease, erythromelalgia, and intermittent claudication, will at once suggest themselves.

The period of childhood has naturally furnished the fewest instances of these disturbances, nevertheless, their occurrence has been recognized in the following order of frequency of incidence: Raynaud's disease, acute circumscribed edema, erythromelalgia, and acroparesthesia. One form of the last that has been overlooked during childhood is acroasphyxia, apparently accounted for by the fact that in some traits it bears striking resemblance to Raynaud's disease. According to E. Kartje, who contributes a valuable paper on this subject in the *Archiv für Kinderheilkunde*, Vol. 53, Nos. 4 to 6, acroasphyxia is characterized by a gradually developing asphyxia of the peripheral portions of the extremities, and differing from the localized asphyxia of Raynaud's disease by its gradual development and by the absence of distinct attacks. In addition there are changes in sensibility and marked trophic disturbances, and in some cases general nervous manifestations. The three classical symptoms of Raynaud's disease are local syncope, local asphyxia, and local gangrene; but cases have been described in which local asphyxia is the only manifestation. These are to be distinguished from cases of true acroasphyxia by the fact that in the latter there is a diminution of sensibility which is only exceptional in Raynaud's disease. On the basis of four cases that he has observed, Kartje delineates the characteristics of acroasphyxia as follows: There is a gradually developing cyanosis of the hands and feet, which is less marked when the atmosphere is warm, and after a hot bath, and also in the lying posture. There is a constant hyperidrosis of varying degree of the cyanotic areas, particularly of their inner surfaces, and also a continuous, though varying, hypoasthesia. The cutaneous temperature is diminished and the cyanotic areas are cool to the touch. The vascular capillary pressure is lowered by the standing and raised by the reclining position. The venous hyperemia and cyanosis are the result of vascular spasm. The galvanic irritability of the nerves is increased in the same manner as is characteristic of tetany. On the strength of these observations Kartje concludes that this disease in spit of its local manifestations is a generalized disorder, characterized by an increased excitability of the nervous system, affecting particularly its vasomotor functions, and manifesting itself mainly by a widespread spasm of the smaller arteries. The etiology is obscurely veiled in all those causes that weaken the nervous system, and the treatment includes measures that improve the general and particularly the cutaneous circulation, such as warm baths, warm applications to the extremities, and massage. The application of the constant current is effective in promoting dilatation of the deeper as well as of the cutaneous vsesels.

PRINTERS' PALSY.

Much interest is nowadays being taken in what are known as occupation diseases. This attitude is, of course, perfectly natural, seeing that in civilized countries the greater part of the population lives in cities and is engaged in employments and crafts which to a greater or less extent predispose to disease. It is needless to state that some of these occupations are extremely injurious to health, in fact deadly, so much so, indeed, that in all progressive countries the law is being invoked to compel employers to use methods to render the work as little harmful to their employees as is possible.

In the *Medical Press and Circular*, August 17, Dr. J. C. McWalter discusses the question of printers' palsy, chronic antimonial poisoning, chiefly from its legal aspect. The British Workmen's Compensation Act has made such a consideration necessary in Great Britain, but as yet in this country this aspect of the case does not especially intrude.

The printers' trade may be looked upon as almost dangerous. Oliver in "Dangerous Trades" states that printers experience a death rate at the various age groups which is above the standard. Their mortality figure is 1,096 as against 602 for agriculturists. They have a high death rate from phthisis and from diseases of the nervous, circulatory, digestive, and urinary systems it is above the average. They suffer about one-third less from fatal accidents than do other workers, but they are somewhat more addicted to suicide. According to McWalter the diseases of the nervous, circulatory, and urinary systems are rather due to the antimony contained in type metal, which is an alloy of lead with 25 to 33 per cent. of antimony, than to the lead, although their mortality figure from lead poisoning is represented by 3. McWalter suggests that many of the more obscure and characteristic disorders of printers are due to antimony. The introduction of linotype machines appears to have lessened the amount of plumbism among printers, but evidence is not infrequently found of antimonial poisoning even among linotype operators.

A curious fact is mentioned by the writer that printing offices are notoriously free from cats. It is said that though men have tried to keep them, feeding them with milk, they eventually fall into ill-health. However, they present all the symptoms of acute lead poisoning, their eyes lose their healthy luster, their limbs become paralyzed, and they finally die with brain symptoms.

Whether it be antimony, arsenic, or lead to which may be mainly attributed the unhealthiness of the printer's craft, there is one thing certain, that printing offices are in too many instances unhealthy in themselves. They are usually situated in the most crowded parts of a big city, and are ill ventilated and are generally in an unsanitary condition. They should be spacious, airy, and well ventilated without draughts, they should be kept clean and especially free from dust. The workers therein should abstain from alcohol and drink milk. Baths should be provided on the premises, but food should not be taken there, while on the other hand no person should work on an empty stomach. There is little doubt that in various parts of America regulations tending to conserve the health of employees, and among these printers, are called for. That is one of the benefits, among many, that would follow the establishment of a Department of Public Health in the Central Government at Washington.

THE CUTANEOUS TRICHOPHYTIN REACTION.

Though there are but few skin diseases which are diagnosed more easily by the clinician than are those of the trichophyton group, tinea tonsurans, tinea circinata and tinea sycosis, these diseases may on occasion occur in atypical forms which make their isolation and differentiation matters of some doubt, and renders any improvement in the means of diagnosis a welcome innovation. Although until recent years it has been supposed that ringworm and its allied diseases were diseases localized to the skin, and without constitutional effects, investigations carried on during the past decade have demonstrated that, like diphtheria, while the ringworm infection is local and circumscribed, the constitutional effects thereof may be general. The result of these researches has been the discovery that culture, filtrates of the ringworm microorganisms, known as trichophytin, when injected into persons who are or have been infected with the parasite cause reactions, both general and local, somewhat similar to those produced by tuberculin. The local reaction at the point of injection consists of inflammation and infiltration; the general reaction includes headache, rise of temperature, malaise and muscular pains.

During the past two years the analogy between trichophytin and tuberculin has been emphasized by the results of experiments carried on by Bloch in producing a local reaction by a cutaneous vaccination of trichophytin, a reaction in many ways suggesting that proposed by von Pirquet. In the July number of *The Journal of Experimental Medicine*, Samuel Amberg reports the results of a series of vaccinations with trichophytin in subjects who had suffered from attacks of rigworm, barber's itch, or Dhobie itch previously, and in a large number of control individuals. The results of the investigation were fairly uniform, cases of ringworm infection which had had their attacks as long as twenty-nine years before giving definitely positive reactions. A few cases without obtainable history of ringworm disease also gave the reaction, and a few others with distinct histories were negative.

The vaccinations were made in a manner similar to that proposed by von Pirquet for tuberculin. The trichophytin was obtained by growing the fungi in a three per cent. maltose bouillon for two or three months at room temperature. The growth was then ground up and filtered through a Chamberland filter and the filtrate was preserved in 0.25 per cent. carbolic acid or 0.5 to 1.0 per cent. carbolglycerine. In positive cases the reaction made its appearance often from four to twenty-four hours as a flat red papule the size of a pea, which itched violently. For twenty-four hours this increased in size, attaining a diameter varying in different cases from 4 to 11 mm. and then slowly faded and disappeared within a few days. A brownish pigmentation remained in some cases for several weeks. In some instances a distinct red halo was formed around the papule, appearing about twenty-four hours after vaccination and lasting in the neighborhood of thirty-six hours.

Such a reaction is a refinement of medicine which gives promise of being of some use in diagnosis, especially in determining the significance of a skin lesion long cured. The recognition of an acute tinea trichophyta infection is so simple from its clinical appearance and the microscopical examination of the hair that in such cases a cutaneous reaction is hardly necessary. In cases, however where the identity of a bygone annular skin lesion is under consideration, especially in reference to a possible past specific infection, such a reaction may have a decided application. From the purely academic viewpoint the results of the investigation are of particular interest.

A MIRACLE OF HEALING.

The report of two cases of syphilis treated by the Ehrlich-Hata preparation, given in this issue of the Medical Record by Dr. M. S. Kakels of this city—the first published account of the use of the remedy in this country—is of a nature to shake the therapeutic incredulity of an Osler. Our foreign correspondents have, of course, informed our readers of the trials of the remedy in Germany and of the astonishing results obtained, and our abstract department has contained many notices from the German periodicals, but Germany is a long way off, and the report of desperate cases, albeit only two, treated in this city, and apparently rapidly progressing to a cure, seems more real. Dr. J. A. Fordyce of this city and Capt. H. J. Nichols of the U. S. Army Medical Corps have been making trials of the remedy at the City Hospital during the past summer, at the suggestion of Dr. Flexner, and their report will be published in the near future. It is said also that other American physicians have received small quantities of "606" and the wonders revealed in this first publication will no doubt soon be duplicated. After November 1, when, as we announced last week, the preparation will be on sale in this country, the accounts will, no doubt, be numerous.

We shall then perhaps hear another side, for with the remedy procurable by anybody, it is too much to hope that the precautions which the inventor of this most powerful protoplasmic poison insists upon, will always be observed. Any accidents resulting from the improper use of the remedy cannot in fairness be charged against it any more than can the use of strychnine be condemned because persons have been killed by overdoses. But, as we said in a previous notice of "606," we cannot yet tell what the final outcome will be, even when the remedy is properly used. The drug is retained in the tissues and is gradually taken up by the circulation and distributed to all parts of the body. Being eminently spirillotropic, so long as any of the specific organisms are present these small amounts are absorbed by them to their destruction, but when the drug, continuously set free in the circulation, is no longer absorbed by the spirochetes, is there not a possibility that it will be found to be generally, even though feebly, protoplasmotropic or neurotropic? This possibility should inspire caution, and must cause some disquietude as

one regards the future of this tremendous experiment. However, the drug may not have any evil after-effects. If it does not, the discovery will rank high among the wonders of these wonderful times, as marvelous as those of Pasteur or of Lister or of Behring, the already honored name of Ehrlich will be still more loudly acclaimed, and the believer in the healing power of drugs will be armed with another weapon in his contest against the hope-killing therapeutic nihilist.

Diagnosis by Wassermann's Reaction.

The evolution of a new diagnostic resource may be rendered appreciable if we compare the current literature on the subject with that of, say, one year or more earlier. At the earlier period we may encounter enthusiasm and optimism; at the later period scepticism, caution, and suggested delimitations of the method. All these represent a reactionary stage quite inevitable in the evolution of any new practical problem; and should be succeeded in time by a counter reaction, comprehending all that has actually been achieved, to the exclusion of whatever is beside the mark. As Sobernheim states in the *Berliner klinische Wochenschrift* for July 18, our knowledge of the Wassermann reaction is in urgent need of organization. He refers, naturally, to the bedside significance of the phenomenon. Simplification of technique, increased delicacy of reaction sound plausible to the practitioner, but variation of the test is probably far more significant in securing trustworthy results The greater the number of extracts used the better. Sobernheim would employ at least three, and only when each of these leads to a strong complement fixation would he call the result positive. In other words, this reaction is not a fit subject at present for short cuts. The authority in question has tested a large number of subjects in this manner, evidently with the praiseworthy aim of excluding such findings as "weakly positive," "doubtful," and the like. Doubtful cases cannot be eliminated outright, for it happens at times that the results with three extracts either conflict among themselves, or are all alike questionable in character. But on the whole variation in reagents seems commendable. This policy is familiar in the very simple tests for albumin and sugar in the urine: for in cases in which the reaction is so slight as to be indecisive successive tests with other reagents must solve the problem. A routinist may be satisfied with a single test with which he has had years of familiarity; while a novice, testing a specimen of urine with some of the thirty or more ordinary reagents which reveal the presence of albumin, may arrive at a much closer conception of the degree of albuminuria. Nothing is so ill advised as dependence on a single test. Sobernheim adheres for the present to the belief in a purely diagnostic significance of the Wassermann reaction. Apparently he would not involve it in prognostic or therapeutic considerations.

Serodiagnosis of Echinococcus Disease.

There is already no little literature on the serodiagnosis of unilocular echinococcus cysts and tapeworms; but until quite recently there has been no corresponding report for the multilocular or alveolar echinococcus. At least that is the conclusion reached by Dobrotin of Kasan, who believes that he has reported the first positive finding (in the *Berliner klinische Wochenschrift*, July 11). He obtained the antigen from a unilocular echinococcus in a man. This is a fact of some significance, for it appears to show that the two forms of parasitism causing the cyst formations stand in closer relationship to each other than has been assumed by many parasitologists. The patient had a large tumefaction of the liver, and the diagnosis lay between cancer of the gall-bladder, syphilis, hypertrophic cirrhosis and alveolar echinococcus. The Wassermann reaction for syphilis was negative. A positive result with antigen from a human echinococcus cyst was obtainable; but when antigen from a similar source in a cow was employed, the result was negative. Autopsy confirmed the diagnosis. As alveolar echinococcus is a relatively rare affection, if one must depend upon antigen from a cyst in man, this diagnostic resource can hardly possess more than an episodical value.

Dobrotin's report is followed by one on the same subject by Kurt Meyer, who confines himself to echinococcus disease in general, with no apparent reference to the alveolar type of cyst. He refers to the fact that "tapeworm carriers" sometimes react positively to the test, even when there are no general symptoms; showing that some product of the parasite must have entered the blood. A positive result in one patient lead to the discovery, after much pains, of tapeworm eggs in the feces. Numerous other diagnostic possibilities make this biological reaction second only in interest, among members of its class, to the Wassermann test for syphilis.

News of the Week.

Infant Mortality.—In a forthcoming bulletin of mortality statistics for 1909, to be issued by the Bureau of the Census, attention is drawn to the fact that of the total number of deaths, 732,538, occurring in the Bureau's death registration area, 196,534, or 26.8 per cent., were of children under five years of age, and 140,057 were of infants under one year. The death registration area covers about 55 per cent. of the estimated population of the United States. In general, it may be said that one death out of five during the year 1909 was of an infant under one year, and one in four of a child under five years. The correct statement of infant mortality, however, can hardly be made until there is a more accurate registration of births throughout the United States. The American Association for the Study and Prevention of Infant Mortality, recently formed, has for its object the coordination of all the sanitary agencies available for the special purpose of reducing the number of preventable deaths among infants, and the procuring of reliable statistics is of great importance in such an undertaking. The figures now available show, as was to be expected, a slightly higher death rate among infants in cities, and slightly lower proportions among the rural population, as compared with the registration area as a whole. In a recent report on "Infant and Child Mortality," Dr. Arthur Newsholme, medical officer of the local government board of England, states that infant mortality forms a sensitive index of social welfare and sanitary administration, and that "it is strictly correct to say that a high infant mortality implies a high preva-

lence of the conditions which determine national inferiority."

Car Runs into Ambulance.—Dr. C. H. Byrne, on the house staff of Bellevue Hospital, New York, was painfully injured on September 12, when the ambulance in which he was conveying a patient to the hospital was struck by a Third Avenue car at Twenty-third street. Two policemen accompanying him were badly bruised. The patient was not injured.

More Centenarians.—Mrs. Margaret Boerum of New York, who died recently at the age of 102 years, had lived in this city since childhood and had been in good health until a few days before her death.

Mrs. H. S. Beckwith of Utica, New York, died on September 11, also at the age of 102 years. She was said to be the oldest resident of Oneida County.

In Saginaw, Michigan, Mrs. A. M. Carrow died on September 15, at the reputed age of 117 years.

The International Opium Conference.—At the request of the Chinese Government, the meeting of this conference, which it was proposed to hold this month, has been postponed for a year. The conference is to formulate a plan for the suppression of the traffic in opium within a given period. The Chinese Government is not yet ready to take up the question.

Charitable Bequests.—St. Mary's Free Hospital for Children, New York, receives a bequest of $10,000 under the will of the late Mrs. Sarah Titus Zabriskie, who died recently in Newport.

By the will of Mrs. Mary Nevins Mayo, who died recently in New York, the residue of her estate, amounting to about $100,000, will be divided equally between St. Luke's Hospital and the Home for Old Men and Aged Couples, subject to the life interest of another person.

The Marlboro Hospital of Marlboro, Massachusetts, will receive about $20,000 from the estate of the late Miss Hannah E. Bigelow of that city.

Dr. John A. Mead of Rutland, Vt., was elected Governor of his State on the Republican ticket, on September 6. Dr. Mead, who is a graduate of the College of Physicians and Surgeons of New York (1868), retired from practice some time ago, and at present fills the office of Lieutenant-Governor of Vermont.

The American Electro-Therapeutic Association held its Twentieth Annual Convention at Saratoga Springs, N. Y., September 13, 14, and 15. There was a large attendance and the full program of scientific papers was read and brought out free discussion. The following officers were elected for the ensuing year: *President,* Dr. Frederick de Kraft, New York; *Vice-Presidents,* Drs. F. Howard Humphris of London, and Frank B. Granger of Boston; *Treasurer,* Dr. Emil Heuel of New York; *Secretary,* Dr. J. Willard Travell of New York; *Registrar,* Dr. Frederick M. Law of New York; *Trustees for Three Years,* Drs. Charles R. Dickinson of Toronto and Thomas D. Crothers of Hartford, Conn.

The Southern Medical Association will hold its annual meeting at Nashville, Tenn., on November 8, 9, and 10, 1910.

The Colorado State Medical Society will hold its annual meeting at Colorado Springs on October 11, 12, and 13, 1910. Dr. A. C. Magruder of Colorado Springs is chairman of the committee on arrangements.

The Medical Society of the Missouri Valley, at its annual meeting at Council Bluffs, Iowa, held recently, elected the following officers: *President,* Dr. Donald Macrae of Council Bluffs; *Vice-Presidents,* Dr. J. M. Bell of St. Joseph, and Dr. J. M. Banister of Omaha; *Treasurer,* Dr. Thomas B. Lacey of Council Bluffs; *Secretary,* Dr. Charles Wood Fassett of St. Joseph. The oration in surgery was delivered by Dr. Norvelle W. Sharpe of St. Louis, his subject being "Fractures of the Femur." Dr. George H. Hoxie of Kansas City gave the oration in medicine, "Arthritis" being the subject. The presidential address, comprising a review of progress in obstetrics, was delivered by Dr. A. B. Somers. The next meeting will be held at St. Joseph in March, 1911.

Obituary Notes.—Dr. Charles Cook Ransom of New York, a graduate of the Medical Department of the University of Buffalo, New York, in the class of 1879; a member of the American Climatological Association, the American Medical Association, the Academy of Medicine, and the New York State and County Medical Societies, and visiting physician to the City Hospital, of which he was also an alumnus, died suddenly on September 13, at the Faxton Hospital, Utica, N. Y., following an operation for intestinal obstruction, aged 50 years.

Dr. J. Frank Gillespie of New York, a graduate of the College of Physicians and Surgeons of Baltimore in the class of 1897, physician to the Out-patient Department of Lebanon Hospital, died at his home on September 12, aged 41 years.

Dr. George F. Perry of Hamilton, Texas, a graduate of the Medical Department of Washington University, St. Louis, in the class of 1875, died at Colorado Springs on August 30.

Dr. Milan A. Gates of Ronceverte, West Virginia, a graduate of the Detroit Medical College in the class of 1880, died at his home of locomotor ataxia on September 10, aged 55 years.

Dr. Isaac Wood of Kingston, Ontario, Can., a graduate of the Faculty of Medicine of Queen's University, Kingston, in 1892, died suddenly on September 1, aged 57 years.

Dr. William H. Drake of Windsor, Ontario, Can., a graduate of the Medical Department of Victoria College, Coburg, died at his home on September 6.

Dr. D. T. Robertson of Lennoxville, Quebec, Can., a graduate of the Medical Department of McGill University, Montreal, Can., in 1867, died at his home on September 7.

Dr. Nathaniel T. Dulaney of Blountville, Tennessee, a graduate of the Jefferson Medical College, Philadelphia, in the class of 1856, a member of the Tennessee State Medical Society, of which he was a former president, died at his home on September 3, aged 76 years.

Dr. William B. Sanford of Memphis, Tenn., a graduate of the Medical Department of Vanderbilt University, Nashville, in the class of 1880; a member of the American Medical Association, the Mississippi Valley Medical Association, the Mississippi and Tennessee State Medical Societies, the Tri-State Medical Association, and the Memphis & Shelby County Medical Societies, and professor of obstetrics in the College of Physicians and Surgeons, Memphis, died in Colorado Springs, of erysipelas, on September 1, aged 53 years.

Dr. Richard K. Gregory of Greensboro, N. C., a graduate of the Medical Department of New York

University in 1860, a surgeon in the Confederate Army during the Civil War, died at his home on September 10, aged 74 years.

Dr. Marcus Rosenwasser of Cleveland, Ohio, a graduate of the University of Wurzburg, Bavaria, in 1867; formerly professor of obstetrics at the Wooster University Medical, and recently professor of the diseases of women in the Cleveland College of Physicians and Surgeons; consulting gynecologist to the City, Mt.
